There are many varieties of odorants, but a universally accepted structure-activity relationship of these has not been established. Yet, there is evidence that odor may involve specific receptor interactions (3), suggesting that structural properties of odorants may be important in eliciting specific odor sensations.

Feeling Factors

"Mouth feel" factors are critical in flavor perception. Examples include astringency, pepper bite, menthol cooling, and texture (e.g., softness or hardness as in candy). Sensations, such as crunch after biting into a crisp stick of celery or an apple, contribute to the overall flavor of foods. These mouth feel factors are also important in improving the organoleptic qualities of pharmaceuticals.

FLAVORING AGENTS

Flavoring agents may be classified as natural, artificial, or natural and artificial (N&A) by combining the all-natural and synthetic flavors (4). Pharmaceutical flavors are available as liquids (e.g., essential oils, fluid extracts, tinctures, and distillates), solids (e.g., spray-dried, crystalline vanillin, freeze-dried cinnamon powders, and dried lemon fluid extract), and pastes (e.g., soft extracts, resins, and so-called concretes, which are brittle on the outside and soft on the inside). Liquid flavors are by far the most widely used because they diffuse readily into the substrate. They are available both as oily (e.g., essential oils) or nonoily liquids. Their texture is generally dependent on the solvent within which they are prepared. Fluid extracts may contain a single ingredient or a variety of compounded ingredients. Tinctures are obtained by maceration or percolation of specific herbs and spices in alcohol.

Essential oils boil at elevated temperatures, but many cannot be directly distilled without decomposition. Vacuum, steam, and fractional or molecular distillation are often used for their manufacture. Fractional distillation removes traces of water, resinous materials, colors, terpenes, and sesquiterpenes from the distillate. This process improves solubility and enhances flavor intensity. Sesquiterpeneless oils are more soluble than terpeneless oils because of the removal of head and tail fractions (e.g., waxy residues). Most common sesquiterpeneless oils used in the pharmaceutical industry include oil of orange and oil of lemon.

Oils and juices are obtained from plant sources by expression. Citrus essential oils are almost exclusively obtained by this method. Thoroughly washed unripe citrus fruits are cold pressed manually, or mechanically, to rupture oil cells in the rind. The oil is collected by draining and centrifuging. Manual operation is labor intensive and has been replaced by machines.

Natural Flavoring Agents

Natural ingredients have been used since antiquity to flavor foods and to make early “medicines” palatable. Honey was and remains a sweetener and flavoring agent. Wine was used as a crude infusorial in medicinal herbs. Modern use of natural flavors in pharmaceuticals is limited, because they are often unstable and their quality is unpredictable from season to season. The most commonly used natural flavors are terpeneless citrus oils, which are stable if well protected from light and air. A variety of other natural flavors are used in the food and

pharmaceutical industries; some of the more common flavors are described below.

Anise (*Pimpinella anisum*, Umbelliferae)

Anise is a herbaceous annual cultivated extensively in Europe. The essential oil is obtained by steam distillation of dried fruits (seeds). The distillate is a clear-to-pale yellowish oil. It solidifies at low temperatures and has a characteristic sweet licorice-like odor and flavor. Its main constituents include anethol (approximately 90%), methylchavicol, *p*-methoxyphenylacetone, and acetic aldehyde. Anise oil is used frequently at concentrations of up to approximately 3000 ppm in liquid preparations.

Cardamon (*Elettaria cardamomum*, Zingiberaceae)

Cardamon is cultivated in India and Sri Lanka. The essential oil is obtained by steam distillation of comminuted seeds to yield a greenish-yellow liquid with a warm, spicy, aromatic odor and flavor. The main constituents of the oil are limonene, cineol, D- α -terpineol, and terpinyl acetate. Cardamon is generally used at concentrations of approximately 5–50 ppm.

Wild Cherry (*Prunus serotina*, Rosaceae)

Wild cherry is a large tree, native to southern Canada. It is widespread in the United States and Europe. The bark, small branches, and twigs are used to prepare the fluid extract and tincture. The main constituent of wild cherry extract is the glucoside prunasin, which on enzymatic hydrolysis yields prussic acid, glucose, and benzaldehyde. Also present are coumarin, phytosterols, benzoic acid, and fatty acids (e.g., oleic, linoleic, and palmitic acids). It has a characteristic sweet, tart, cherry-like flavor. Wild cherry bark extract is commonly used at concentrations of approximately 50–800 ppm in foods and pharmaceuticals.

Lemon (*Citrus limonum*, Rutaceae)

Lemon is an evergreen shrub or tree native to the Far East; it was introduced to the Mediterranean regions at the time of the Crusades. The leaves, fruits, and rind are used either whole or pressed in foods and in liquid or solid pharmaceutical products. The essential oil of lemon is obtained by cold expression. Approximately 40 constituents have been identified, with 90% being limonene. Fluid extracts and tinctures are obtained from the dried peel.

Lemon petitgrain is obtained by steam distillation of the leaves. For flavoring, it must be terpeneless. The main constituents are D- α -pinene, camphene, D-limonene, dipentene, L-linalol, nerol, and citral. Lemon petitgrain oil is used in a wide variety of applications. Typical concentrations range from 1 to 35 ppm. The essential oil and extract of lemon are generally used at higher concentrations that may range up to 1000 and 10,000 ppm, respectively. All lemon oil derivatives have the characteristic lemon odor and a slightly bitter flavor.

Orange, Bitter (*Citrus aurantium*, Rutaceae)

Bitter orange is a tall tropical tree that can grow up to approximately 10 m (33 ft.) high. The tree is native to the Far East and is cultivated extensively throughout the Mediterranean, Guinea, the West Indies, West Africa, and Brazil. The leaves and twigs produce essential petitgrain oil following steam distillation. *Neroli bigarade* essential oil is produced from the blossoms by steam distillation. The peel is expressed and steam distilled to produce essential oil of orange. The main constituent of orange oil is D-limonene, with various acids, aldehydes, and diesters. Essential oil of orange is widely used in foods and pharmaceuticals at concentrations of up to 500 ppm.

Orange, Sweet (*Citrus sinensis*, var. *aurantium dulcis*, Rutaceae)

Sweet orange is an evergreen tree that grows to approximately 6 m (20 ft.) high. It is generally of oriental origin and is cultivated extensively in the Mediterranean, Florida, and California. A petitgrain oil is obtained from the leaves and twigs, but its production is low because of limited use, primarily in the perfumery industry.

Essential oil of sweet orange is obtained by expression. Its physical–chemical properties (e.g., specific gravity, optical rotation, and refractive index) vary according to origin. The oil contains more than 90% limonene, in addition to relatively high quantities of decylic, octylic, nonylic, and dodecylic aldehydes, and citral esters. It has a characteristic odor and a mildly bitter, astringent flavor; it is generally used at concentrations of up to 500 ppm.

Peppermint (*Mentha piperita*, Labiatae)

Peppermint is a herbaceous plant that grows to approximately 81 cm (32 in.) high. The essential oil is obtained by steam distillation of the flowering plant tops. It is cultivated in Europe, North and South America, and

Japan. The main constituents of the essential oil are α - and β -pinene, limonene, cineol, ethyl amylcarbinol, menthone, menthol, isomenthol, menthyl acetate, and piperitone. It has a strong mint odor with a sweet balsam taste masked by a strong cooling effect. It is widely used in foods, as well as in liquid pharmaceuticals, to 8000 ppm.

Artificial Flavoring Agents

Unlike natural flavoring agents, synthetic flavors are usually stable. The development of synthetic flavors paralleled the development of instrumental analysis, in which active ingredients in natural flavors are identified and reconstructed synthetically with reasonable accuracy. Exact duplication of a natural flavor is, however, difficult because often minor components are the most important contributors to the overall flavor profile. These minor components are not easily identified. For example, the major components of vanilla are vanillin and ethyl vanillin. However, the flavor nuances of the vanilla bean have never been successfully matched in artificial (synthetic) vanilla.

Natural and Artificial (N&A) Agents

In N&A flavor systems, natural flavors are combined with synthetic ingredients to enhance flavor balance and fullness. These flavors are generally classified according to type and taste sensation. Table 1 contains a list of N&A flavor components that elicit various sensory properties, all of which are commonly used in food and drug compounding. It is not an exhaustive list because manufacturers regard their flavor formularies as proprietary. Many N&A flavors may be chemically and structurally similar, but vary significantly in taste and aroma. Similar flavors from various vendors might vary significantly in composition. Of interest is the fact that a relatively small change in chain length can have a profound impact on flavor type. Minor changes, such as the conversion of allyl benzoate to cyclohexyl esters (e.g., a caproate or valerate), transform a basic cherry flavor to peach or pineapple.

In situ conversion of essential N&A flavor components from one molecular form to another, as a result of ion pairing, is common in food and drug products. Therefore, the inadvertent conversion of flavors between types during drug formulation studies (e.g., effect of pH, salts, and temperature) can present a serious challenge in flavor-quality assessment. The fact that one and the same N&A flavor component can deliver several flavor and odor impressions implies that a blend of several flavor compounds would be preferable. Such blends show improved stability. In addition, flavor impressions from

Table 1 Primary taste and flavor characteristics of typical flavor ingredients

Ingredient	Primary taste			Flavor characteristic
	Sweet	Bittersweet	Bitter	
Allyl benzoate		X		Cherry
Allyl caproate		X		Pineapple
Allyl cyclohexylbutyrate		X		Pineapple
Allyl cyclohexylcaproate		X		Peach/apricot
Allyl cyclohexylvalerate		X		Apple
Allyl phenoxyacetate		X		Honey/pineapple
Anethol	X			Anise
Anisyl alcohol	X			Peach
Anisyl formate	X			Strawberry
Benzyl isobutyrate	X			Strawberry
Benzyl salicylate	X			Raspberry
Cinnamaldehyde		X		Cinnamon/melon
Cinnamyl anthranilate		X		Grape
Citral		X		Lemon
Citronellyl formate		X		Plum
Cyclohexyl caproate		X		Peach/cognac
Decyl formate	X			Grape
Diacetyl	X			Butter
Diphenyl ether	X			Black currant
Ethyl valerate		X		Banana/apple
Eugenol			X	Clove buds
Geraneol			X	Rose-like
α -Ionone	X			Raspberry
Isoamyl salicylate		X		Strawberry
Isobutyl anthranilate		X		Grape/strawberry
Isopropyl valerate		X		Apple
Linalyl anthranilate	X			Orange
Methyl ionone	X			Raspberry/currant
Methyl propionate	X			Black currant
Methyl undecyl ketone		X		Coconut
Musk ambrette	X			Peach
Nerol			X	Rose-like
Neryl acetate	X			Raspberry
Neryl butyrate	X			Cocoa
Propenyl guaethol	X			Vanilla
Propyl isobutyrate	X			Pineapple

Santaly acetate		X		Apricot
Terpenyl butyrate		X		Plum
Tetrahydrofurfuryl propionate		X		Chocolate/apricot
Vanillylidene acetone		X		Vanilla
Yara yara	X			Strawberry

N&A flavor blends are usually not dominated by a single component. For these reasons, single natural and artificial flavor ingredients are seldom, if ever, used alone in a finished product.

Tables 2 and 3 list the components thus far qualitatively identified (4) in two common fruits, the raspberry and the

strawberry. These tables illustrate the complexity in compounding synthetic systems to mimic natural types. For this reason, there has been a steady rise in the use of N&A flavors, in addition to their superior performance, when compared to natural flavors. Also, the quality and uniformity of the N&A flavor is greater than that of natural

Table 2 Natural components of raspberry aroma

Acids	Carbonyls	Esters	Alcohols
Acetic	Acetaldehyde	Butyl acetate	1-Butanol

	2-Pentanal	Methyl caprylate	
	Propanal	Propyl acetate	

(From Ref. 4.)

flavors, and lower concentrations of N&A flavors are often used to achieve the same effect as obtained with natural flavors. Table 4 shows a typical formulation of a commercial N&A strawberry flavor. It contains a small proportion of natural flavors; the bulk of the ingredients are synthetic.

Another advantage of N&A flavors is the broad spectrum of flavoring agents from which the formulator can develop an entirely new flavor system that is unique, not available naturally. A flavor extensively used in foods and pharmaceutical products is tutti-frutti—bubble gum (Table 5).

In summary, there are a variety of flavor types: natural, synthetic, and semisynthetic. Appropriate use concentrations depend on many factors, including product characteristics, such as composition, physical state, shelf life, pH, processing temperature, storage conditions, and reactivity of components. Flavor concentrations also depend on the market sector for which the product is targeted. The age of the user and the mode of use are two examples of user-dependent variables that have significant bearing on the type, concentration, and nature of the flavor selected for product development.

FLAVOR SELECTION IN PHARMACEUTICAL PREPARATIONS

A number of criteria are used to select flavors during formulation. Different flavor concentrations produce

highly subjective sensations. Specific requirements for balance and fullness are dependent, in part, on the drug substance and the physical form of the product. For this reason, when selecting a flavor system, the compounding pharmacist must take into account several variables upon which a desired response would depend. Some of these are product texture (e.g., viscosity of formulation, solid or liquid), water content, base vehicle or substrate, and taste of the subject drug. Notable specific examples to consider are:

- Immediate flavor identity from the formulation as it is ingested;
- Compatible mouth feel factors and rapid development of a fully blended flavor in the mouth during ingestion of the product;
- Absence of “off” notes in the mouth and a mild transient aftertaste during ingestion of the product.

The selection of a flavor system, thus, requires an extensive evaluation of a number of organoleptic qualities. Vehicle components within which the drug is presented have a significant bearing on the performance of the flavor system. Of these, the sweetener is perhaps the most relevant.

Sweeteners

The most commonly used sweeteners are sucrose, glucose, fructose, sorbitol, and glycerin. Using sucrose (sugar) as a standard, with 100 units of sweetness, Table 6 lists the

Table 3 Natural components of strawberry aroma

Acids	Esters	Alcohols

relative intensities of other sweeteners. Sweetness intensity changes with concentration. It has been estimated (5) that the sweetness of glucose relative to cane sugar is 53 at a concentration of 8% but increases to 88 at a concentration of 35%. Sweetener intensity increases with concentration but reaches a maximum where feeling factors become more prominent. Sugar (sucrose), at a concentration of 30%, is intensely sweet. Yet, its sweet

intensity at concentrations 50% or higher is not perceptibly different, although distinct mouthfeel characteristics (e.g., syrupy, salivation) become pronounced. This is due to osmotic effects on mucous membranes within the oral cavity.

Glycerin, glucose, sorbitol, and sucrose have limited use in solid dosage forms (e.g., tablets) because the materials are hygroscopic. Mannitol is used more often in

Table 4 A typical formula composition of natural and artificial strawberry flavor

Ingredient	Parts by weight
Amyl acetate	34.0
Amyl butyrate	15.0

tablet manufacture. Besides being less hygroscopic, it has a negative heat of solution. For this reason, chewable tablets containing mannitol have a pleasant cooling sweet taste, which complements flavor quality. The artificial sweetener saccharin is widely used in foods and pharmaceuticals. It is approximately 350 \times as sweet as sugar. It is sweet at very low concentrations (equivalent to about 5–10% sugar) but bitter at higher concentrations. Approximately 20% of the population are “saccharin sensitive;” that is, they perceive saccharin to be bitter even at low concentrations. Upon repeated tasting, saccharin becomes less sweet and increasingly bitter. By the third or fourth tasting, solutions of relatively low concentrations are often no longer sweet to the saccharin-sensitive person.

Table 5 Formula and composition of natural and artificial tutti-frutti flavor

Ingredient	Parts by weight
Amyl acetate	300.0

Total	1000.0

(From Ref. 4.)

The artificial sweeteners, cyclamate and aspartame, are about 30 \times as sweet as sugar, but like saccharin, their sweet-bitter profiles are concentration dependent. Aspartame does not have a significant bitter aftertaste when compared to saccharin and has gained in popularity. Cyclamates were banned in the 1970s because of carcinogenic concerns, which have, subsequently, been shown to be overstated.

Monoammonium glycyrrhizinate has a lingering sweet aftertaste, which can be exploited for taste-masking products with a mildly bitter aftertaste. It is also effective in enhancing chocolate flavor. Glycerin is commonly used for its solvent effect on many compounds, as well as its humectant effect. Sugar syrups promote significant “cap-locking”—the crystallization of the sugar on the cap and bottle thread, but the addition of glycerin (10–20%) minimizes this effect. Glycerin is seldom used as a single sweetener in pharmaceuticals because it has a characteristic mouth-warming and burning effect.

Flavor Enhancers and Potentiators

Flavor enhancers are used universally in the food and pharmaceutical industries. Sugar, carboxylic acids (e.g., citric, malic, and tartaric), common salt (NaCl), amino acids, some amino acid derivatives (e.g., monosodium glutamate—MSG), and spices (e.g., peppers) are most often employed. Although extremely effective with proteins and vegetables, MSG has limited use in pharmaceuticals because it is not a sweetener. Citric acid

Table 6 Intensity values for frequently used sweeteners

Sweetener	Intensity
Sorbitol	60
Mannitol	50
Hydrogenated starch hydrolysate	30–40
Maltitol solution	70–80
Maltitol	90
Xylitol	100
Erythritol	60–70

Sucrose	100
Fructose	117
Maltose	30

(From SPI Polyols, Inc., Polyols Comparison Chart, Revised 6/99.)

is most frequently used to enhance taste performance of both liquid and solid pharmaceutical products, as well as a variety of foods. Other acidic agents, such as malic and tartaric acids, are also used for flavor enhancement. In oral liquids, these acids contribute unique and complex organoleptic effects, increasing overall flavor quality. Common salt provides similar effects at its taste threshold level in liquid pharmaceuticals. Vanilla, for example, has a delicate bland flavor, which is effectively enhanced by salt.

Taste-Masking Agents

The flavoring industry has many proprietary products purported to have excellent taste-masking properties (4), which have been used with some success. Yet, there are a number of natural and artificial flavors that can be generally described to possess similar taste-masking effects (Table 7).

Table 7 Agents for masking and complementing the basic tastes

Basic taste	Masking agent
Sweet	Vanilla, bubble gum, grape, other fruits
Acid	Lemon, lime, orange, cherry, grapefruit
Metallic	Berries, mints, grape, marshmallow, gurana
Bitter	Licorice, coffee, chocolate, mint, grapefruit, cherry, peach, raspberry, orange, lemon, lime

Of the many tastes that must be masked in pharmaceuticals, bitterness is most often encountered; to mask it completely is difficult. A tropical fruit has been used for centuries in central Africa to mask the bitter taste of native beers. This so-called “miracle berry” contains a glycoprotein that transiently and selectively binds to bitter taste buds. Due to stability challenges, attempts to isolate the compound for commercial exploitation have been unsuccessful. Yet, many fruit syrups are relatively stable in pharmaceuticals if formulated with antimicrobial preservative agents. Syrups of cinnamon, orange, citric acid, cherry, cocoa, wild cherry, raspberry, or glycyrrhiza elixir can be used to effectively mask salty and bitter tastes in a number of drug products (6). The extent to which taste-masking may be achieved is not usually predictable due to complex interactions of other flavor elements in these products. The degree to which bitterness may be masked by these agents ranks in a descending order: cocoa syrup is most effective, followed by raspberry syrup, cherry, cinnamon, compound sarsaparilla, citric acid, licorice, aromatic elixir, orange, and wild cherry.

Sour and metallic tastes in pharmaceuticals also can be reasonably masked. Sour substances containing hydrochloric acid are most effectively neutralized with raspberry and other fruit syrups. Metallic tastes in oral liquid products (e.g., iron) are usually masked by extracts of gurana, a tropical fruit. Gurana flavor is used at concentrations ranging from 0.001 to about 0.5% and may be useful in solid products as well (e.g., chewable tablets and granules).

FLAVOR MODIFICATION TECHNOLOGIES

Solubility-Limiting Methods

Many drugs are reasonably soluble in water and ionize extensively at physiologic pH. Drugs with an offensive taste usually demonstrate negative organoleptic properties after dissolving in saliva during ingestion. Chemical modification, such as derivatization or lipophilic counterion selection, where possible, may be an effective method for reducing aqueous solubility and taste. This is exemplified by erythromycin, a partially soluble, bitter-tasting macrolide anti-infective. The solubility of erythromycin monohydrate is approximately 2 mg/mL in water at a pH of approximately 7. When converted to erythromycin ethylsuccinate, the aqueous solubility of the drug is less than 50 µg/mL. This form is practically tasteless as a ready-made liquid or a chewable tablet. The rate of dissolution in body fluids (e.g., saliva) may be further reduced by controlling formulation pH, solids content,

and temperature. This technique can be applied to a number of drugs whose taste profiles are dependent on aqueous solubility.

Vesicles and Liposomes

Host–guest systems (7) (e.g., phospholipids and certain surfactants) form spherical or ellipsoidal, closed, bilayer structures called vesicles. These structures often comprise several compartments within which a drug could be trapped, either as a solution or a dispersion. Under various conditions, these vesicles form closed systems, which are ideal vehicles for taste masking or for modulated release of drug in vivo. It is a challenge to formulate drugs with these flavor-masking methods without altering the regulatory status of the product (e.g., chemical designation of the active substance, in vitro dissolution kinetics, physical or chemical stability, and bioavailability). Various manufacturers (e.g., American Lecithin Company, Oxford, Connecticut) offer a complete line of phospholipids (purified and solubilized in various carrier systems) for use in the food and pharmaceutical industries.

Microencapsulation and Coated Systems

Recently, a great deal of attention has been focused on the usefulness of coated fine particles in achieving pharmaceutical objectives. By coating drug particles with an appropriate polymer system, desirable properties can be imparted to the dosage form, eliminating undesirable properties, such as taste. Coating drug particles significantly modulates drug release while improving taste, stability, and other handling characteristics (e.g., flow and compression). Commercial particle coaters make it possible to coat fine drug particles, achieving slow release and taste masking in oral formulations. Examples for which particle coating has been used to introduce unique line extensions to the marketplace include Theo-Dur[®] and Depakote Sprinkle[®]. In the case of Theo-Dur[®], theophylline is sprayed onto sugar beads followed by a polymer to control drug release. By encapsulating a drug substance, this process prevents interaction of the drug with taste receptors, thus eliminating bitterness. Other frequently used microencapsulation methods include spray drying, spray congealing, coacervation and phase separation, interfacial polymerization, and extrusion.

Complexation and Chemical Modification

The use of ion exchange resins to form drug adsorbates for sustained release (8, 9) was closely associated with

Strassenburgh Laboratories, an affiliate of Pennwalt Corporation, which was granted several patents in this area (10, 11). Their first significant application involved amphetamine adsorbed onto a sulfonic acid cation exchange resin (Biphedamine[®]) for use in appetite suppression (12). Over the years, several products have been introduced commercially since the initial work with amphetamine (13–16); examples include Ionamin[®] (phentermine: Medeva Pharmaceuticals, Inc.), Tussionex[®] (hydrocodone polistirex and chlorpheniramine polistirex: Medeva Pharmaceuticals, Inc.), and a variety of cough-cold products, including phenylpropanolamine, chlorpheniramine, and dextromethorphan (17). This technology is applicable to taste masking as well.

The mechanism of drug release from the sustained–release complex (e.g., an ion exchange resinate consisting of a drug with a bitter taste) is ideal for liquids, when formulated either as granules for reconstitution or ready-made suspensions. By retaining a low counter-ion concentration in the product, almost all of the drug may be retained in the matrix, so that upon ingestion, ions of the body trigger the release mechanism through a dynamic equilibration process. Slow equilibrating complexes that provide low diffusivity of drug to the taste buds (e.g., low aqueous solubility of the drug) can eliminate bitterness and other offensive organoleptic drug properties. Other complexation phenomena employed in formulation work for flavor enhancement are: inclusion complexes (e.g., cyclodextrins and their derivatives), matrices, and physical complexes with waxy substances (e.g., polyethylene glycols).

More recently, pharmaceutical manufacturers have introduced various technologies for coating drug particles with semipermeable polymeric membranes designed to provide controlled release in vivo. Coatings of neat drugs and their adsorbates (18–21) combined controlled–release characteristics with the benefit of taste masking, caused by the effective reduction of dissolved drug concentrations in the mouth. Taste evaluation of a variety of these preparations showed a significant reduction in bitterness (19–21), suggesting that coatings and adsorbates have potential in the flavor enhancement of drugs with offensive tastes.

CONCLUSIONS

The use of flavors and flavor modifiers in pharmaceutical formulations is of considerable importance in promoting drug products. Flavors are also key factors in promoting patient compliance, because products with offensive taste

are likely to be objectionable. Taste sensations are, however, wholly subjective, and of the many objective methods thus far used, none can adequately and completely characterize taste and aroma sensations without some bias.

It is also certain that a fair proportion of the population is indifferent to taste and lacks the acuity necessary for distinguishing small differences in taste and aroma between samples (22, 23). Furthermore, clear flavor performance differences can be obtained during pharmaceutical product development, by techniques designed to promote taste acceptance. The use of flavors, flavor modifiers, and other methods for flavor enhancement, such as physical and chemical manipulations of drugs, may be potential methods for the development of products with superior market preference characteristics.

ACKNOWLEDGMENTS

The authors are grateful to Akwete L. Adjei and Richard Doyle for their contributions to the 1st Edition of this article and to Tracy B. Lynch for her assistance in the final preparation of this manuscript.

FLAME PHOTOMETRY

Thomas M. Nowak

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

INTRODUCTION

The use of flame photometry as a quantitative tool can be traced to work by Kirchhoff and Bunsen in the early 1860s (1). Its modern history begins, however, in the 1940s, when instruments became available that successfully addressed the problems of reproducible sample introduction and detection. Flame photometry soon developed into a reliable analytical technique for the determination of several cations of pharmaceutical interest, notably sodium, potassium, and lithium. The technique is useful in the analysis of bulk drugs, dosage forms, and clinical samples such as blood and urine.

This article focuses primarily on “traditional” low-temperature flame photometry. High-temperature flame photometry has evolved into separate techniques, typically identified by their temperature sources (e.g., inductively coupled plasma-atomic emission spectrometry, ICP-AES 2). Some references to other related analytical tools, including high-temperature flame photometry, are made here to establish perspective.

PRINCIPLE OF OPERATION

Flame photometry, as with other spectrophotometric techniques, takes advantage of the unique spectral properties of each element when it is energized about its ground state to an excited state. When the energized electrons return to their ground state, they emit light at discrete wavelengths. The emitted light is optically filtered and photometrically detected. Quantification is based on a calibration curve of emission of intensity versus analyte concentration.

The analyte is introduced as a homogeneous solution into the flame as an aerosol. The flame provides sufficient energy to yield free gaseous atoms in the ground state. The amount of energy provided by the flame additionally allows a small fraction of available atoms to be energized above the ground state. Typically, the flame is produced using a mixture of air and propane (or air and butane), which provides a temperature of approximately 1900°C

(3). In high-temperature flame photometry, the percentage of atoms is increased. In both high- and low-temperature flame photometry, the atoms of interest are energized as a result of the temperature of the flame, furnace, or plasma. This is in contrast to atomic absorption spectrophotometry, which uses light of a discrete wavelength to energize the analyte atoms. The temperature of the flame in atomic absorption is primarily used to yield a sufficient number of free atoms in their ground state.

The general viability of low-temperature flame photometry depends on two factors. First, the alkali and alkaline earth metals of analytical interest (sodium, potassium, lithium, cesium, rubidium, magnesium, calcium, strontium, and barium) reach their excited states at relatively lower temperatures than do most other elements. Second, the emission wavelengths offer enough resolution such that optical filtering can be accomplished at a relatively low cost.

INSTRUMENTATION AVAILABLE

The first commercially available flame photometer was introduced in the 1940s by the Perkin–Elmer Corporation. In 1948, Beckmann Instruments, Inc., introduced a flame attachment that could be used with their popular model D. U. spectrophotometer (1). By the late 1950s, instruments had been developed that used lithium as an internal standard to maximize precision. Autodilution features and microprocessor-controlled operations became widely used options in the 1970s. The most recent significant development was the introduction of cesium as the internal standard, by Instrumentation Laboratory, Inc. (Figs. 1–3). This development makes concurrent lithium determinations more practical.

With the use of fuels that produced hotter flames, earlier flame photometers became useful for analyzing elements beyond the alkali and alkaline earth metals. The development of atomic absorption spectrophotometers in the late 1960s provided the analytical chemist with a better tool for many of these applications. Later developments in high-temperature flame photometry narrowed the analytical applications

Fig. 1 Flame photometer using cesium as the internal standard. (Courtesy of Instrumentation Laboratory, Inc.)

of low-temperature flame photometry even further. The utility of the flame photometer to the clinical chemist, however, was not diminished until the development of ion-selective electrode (ISE) analyzers, which began in the mid-1970s. Although the niche for traditional flame photometers has narrowed, owing to the emergence of other technologies, flame photometry is the method of choice in a variety of applications.

APPLICATIONS

The analysis of clinical samples represents a typical application of flame photometry. Concentrations of sodium, potassium, and lithium in blood and urine are well within instrument working ranges. The specificity of the technique is a distinct advantage. Automated models of flame photometers, available during the past 25 years, are typically designed to serve the needs of the clinical chemist. Instrument calibration protocols are built into instruments to facilitate the timely analysis of sodium, potassium, and lithium in clinical samples.

(Courtesy of Instrumentation Laboratory, Inc.)

Other applications in the scope of pharmaceutical analysis include the analysis of sodium and potassium in injectable formulations and of trace amounts in bulk drugs, in dissolution experiments, and in content uniformity testing (4).

There are at least 14 USP, NF, or BP bulk drug monographs that use flame photometry either to control sodium potassium as an impurity or to assay for the primary ion (Table 1) (5, 6). An external standard method procedure is referenced in both the USP and the EP. The USP chapter, "Flame Photometry for Reagents," first appeared in USP XVII (1965) (7).

There are at least 25 USP or BP formulation monographs that use flame photometry to assay ions of interest (Table 2) (8). This technique is applicable to a variety of situations because of the relatively low cost per sample (in analyst time, instrument capital expense, and testing supplies); reasonable precision (typical relative standard deviation values are 0.6% for sodium, 1% for potassium, and 2% for lithium); low sample volume

requirements (as low as 10 µl in some cases); and ease of operation.

COMMON SOURCES OF ANALYTICAL ERROR

In most applications, interferences are rare. Each new matrix requires some investigation, however, because problems can occur, especially when one element is to be determined in the presence of a large excess of another element. In a typical analysis, a liquid sample is diluted in a 1:100 or 1:200 ratio with diluent containing a lithium or cesium salt. Adequate dilution of a sample represents one of the most effective means of overcoming interference problems. Generally, samples are diluted to contain less than 10% by weight of total solids (not including the dilution with internal

standard). If dilution does not eliminate interference, atomic absorption should be used. It offers advantages for the determination of magnesium, calcium, and zinc in many matrices (9, 10). In some instances, however, sample pretreatment can make it possible to obtain good results with flame photometry (11).

With the development of ion-selection electrode technology (ISE), a means became available to directly measure (no dilution) sodium and potassium in the presence of clinical samples containing a significant amount of protein or lipids. Because of nonaqueous components in the sample matrix, the volume occupied by sodium and potassium ions is less than the total volume of the sample. When using a technique that requires dilution (flame photometry) or utilizes dilution (indirect-ISE), a lower concentration is observed than that obtained with direct-ISE. In as much as the bias can be clinically significant (up to 7% in some instances) it is important that the method used be taken into account (12, 13).

THE FUTURE

Low-temperature flame photometry is a mature technology and not likely to see many significant new applications. Advances in high-temperature flame photometry and atomic absorption techniques appear, well-suited to most of the new challenges in elemental analysis. Indeed, most of the pioneer commercial suppliers of flame photometry instrumentation have abandoned the market. Clinical laboratories are using ion-selective electrode analyzers more and more for

FILTERS AND FILTRATION

Maik W. Jornitz

Sartorius Group, Germany

INTRODUCTION

The separative process of filtration is widely used within the biopharmaceutical industry to remove contaminants from liquids, air, and gases, such as particulate matter but especially microorganisms. Microorganism removal is either required to achieve a sterile filtrate or, if the pharmaceutical product is thermally sterilized, to reduce the bioburden and, therefore, avoid elevated levels of endotoxins—the debris of gram-negative organisms (1).

There are many filter configurations within the industry, such as sheet or modular depth filter types for prefiltration purposes, flat filter membranes mainly for microbial detection and specifications, and, most commonly, filter cartridges containing either depth filter fleeces or membrane filters. Such membrane filters are available in a large variety of membrane polymers for different applications. These materials are discussed later in the chapter.

Sterilizing grade membrane filters are defined by the FDA Guideline on Sterile Drug Products Produced by Aseptic Processing (2) by being able to retain 10^7 *Brevundimonas diminuta* (formerly *Pseudomonas diminuta*) organisms per square centimeter of filtration area at a differential pressure of 2 bar (3). Such retention efficiency has to be validated, using the actual drug product and the process parameters, due to the possibility of an effect to the filters compatibility and stability and/or the microorganisms size and survival rate (4, 5). Performing these so-called product bacteria challenge tests became a regulatory demand (6) and, therefore, belong to a standard filter validation. Before these challenge tests can be performed, several parameters, for example, bactericidal effects of the product, have to be evaluated. The recently published PDA Technical Report 26 (7) describes the individual parameters—the possible effects and mechanisms to be used to perform challenge tests. Additionally, the report discusses filtration modes, sterilization, and integrity testing.

FILTER TYPES

One can differentiate filters in different distinctive types, commonly in membrane and depth filters. Depth filters

retain contaminants within the depth of the filter matrix. Contaminants have to move through the tortuous path of the fiber matrix and eventually will collide with a fiber and separate from the medium. Due to the depth retention, such filters have a very high dirt-load capacity and are able to separate a high load of contaminants of different sizes. Depth filters are utilized for coarse particle removal, polishing filtration, and, especially, to protect final membrane filters reverse osmosis or deionizing units. Depth filters can greatly enhance the membrane filter's total throughput capability. Therefore, before utilizing a filtration process in a new application, filterability trials are commonly performed to evaluate the optimal prefilter–final filter combination to achieve the lowest cost per liter ratio and highest yield. Initial filterability tests are done with 47-mm composites (flat filter discs of the filter cartridge device to be used). Having found the optimal combination of prefilter retention to final filters pore size, pleated small-scale devices are used to achieve appropriate filter sizing parameters. Filterability trials are performed with automatic test rigs, which utilize a balance as a load cell to measure the filtrate collected. Commonly, the balance is connected to a computer system, which uses a specific software showing the flow rate, total throughput, and differential pressure graphs and offer a report including such.

As depth filters retain contaminants within the fiber matrix, membrane filters are surface retentive filters and, therefore, have the distinct disadvantage to clog faster. The filter industry, therefore, pleats such membranes to install a higher effective filtration area into a filter device. Still, such effort has its limitation, due to a maximum allowable pleat density. Having reached the limit, the only option is the use of prefilters or membranes of different pore sizes to gain a fractionate retention and, therefore, a prolonged lifetime of the filter. Some membrane filter configurations have such membrane or depth filter prefilters built into the filter cartridge. This is convenient for the filter user in respect to lowered hardware costs. Additional prefilter housings are not necessary. In comparison to depth filters, membrane filters have a narrow pore size distribution, which results in a by far sharper retention rate. Pore size ratings are facilitated to differentiate membrane filters

and the performance of such. Commonly, a sterilizing grade filter is labeled 0.2 μm when it retains 10^7 B.diminuta/cm². Another advantage and necessity of membrane filters is the fact that these are integrity testable. Therefore, flaws or defects can be detected, which is critical, due to the function of membrane filters, mainly in separating microorganisms from pharmaceutical solutions.

Membrane filters are made in a wide variety of pore sizes (Fig. 1). The effective pore size for membranes vary, and membranes can be used in reverse osmosis (RO), nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF). RO membranes are widely used in water treatment to remove ionic contaminations from the water. These membranes have an extreme small pore size and, therefore, require excellent pretreatment steps to reduce any fouling or scaling of the membrane, which would reduce the service lifetime. RO membranes are used by extensive pressures on the upstream side of the filter membrane to force the liquids through the pores.

The retention ratings of UF filters are also not measured in pore size but rather in MWCO (molecular weight cut-off), i.e., the molecular weight of the substance to be retained. UF filter systems are most often used in cross-flow (tangential flow) systems. The feed stream is directed over the actual membrane to diminish blockage of the membrane. Depending on the pressure conditions, the fluid (permeate) penetrates through the membrane, whereby the remaining fluid is recirculated (retentate). UF filter systems find applications in concentration, diafiltration, and removal steps within pharmaceutical downstream processing. MF can be used as dead-end filtration (the feed is directed to the membrane, resulting into a filtrate, separated from the contaminant) or tangential flow mode. The tangential flow characteristic for MF is commonly used for cell or cell debris removal in downstream processing. MF membranes typically differ from UF membranes in

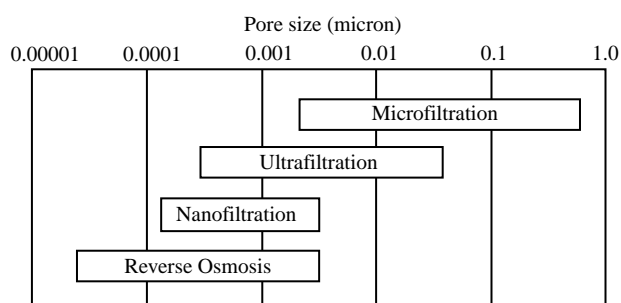

Fig. 1 Typical pore sizes for membranes used in reverse osmosis, nanofiltration, ultrafiltration, and microfiltration.

Fig. 2 Skin layer structure of a UF membrane. (Courtesy of Sartorius AG.)

the morphology of the membrane's cross-sectional cut. The symmetry of sterilizing-grade microfilters usually ranges from being uniform to being slightly asymmetric. Ultrafilters, on the other hand, are highly asymmetric, with the rejecting layer consisting of a tight skin (0.5–10 to μm thick) supported by a thick spongy structure of a much larger pore size (Fig. 2).

MF is used in a large variety of filtration applications, from fine cut prefiltration to sterilizing grade filtration in aseptic processing. Often sterilizing grade filters are the terminal step before filling or final processing of the drug product. MF is available for air and gas applications and liquid clarification or sterilization. For the different applications, specific membrane configurations and materials have been developed.

FILTER MATERIALS

There are a variety of different depth filter and membrane filter materials used within the pharmaceutical processes. Depth filter are fibrous materials: for example, Polypropylene, Borosilicate, or Glassfibre fleeces (Fig. 3). Borosilicate and Glassfibre materials are highly adsorptive and commonly used to remove colloidal substances, like iron oxide from water or colloidal haze from sugar solutions.

Prefilters can also contain membranes instead of fibrous depth filter material. Such membrane material are commonly mixesters of cellulose or pure cellulose acetate. The cellulose mixester filter material contains a high degree of cellulose nitrate, which again is highly adsorptive. Such prefilters have a very sharp retention rating and, therefore, are used in applications in which the

Fig. 3 SEM of the random fiber matrix of a depth filter. (Courtesy of Sartorius AG.)

contaminant has a narrow size distribution and/or a sterilizing grade filter has to be protected, due to the fact that such a filter cannot be changed during the filtration process. Membrane prefilters, when blocked, can be

exchanged during the filtration process, due to the final filter downstream.

Most commercial UF and NF membranes and many MF membranes are made by the phase-inversion process, where a polymer is dissolved in an appropriate solvent along with appropriate pore-forming chemical agents. The polymer solution is cast into a film, either on a backing or freestanding, and then the film is immersed in a nonsolvent solution that causes precipitation of the polymer. Such membranes are Polyamides, such as Nylon, Polyethersulfon (PESU), or Polyvinylidene fluoride (PVDF). Cellulosic membranes, such as cellulose nitrate, acetate, or regenerated cellulose, are casted as a cellulose–water–solvent mixture onto a belt and transported through heated tunnels. The resulting evaporation process produces the porous structure of the membrane seen in Fig. 4.

Other techniques for membrane formation include stretching the polymeric film, commonly Polytetrafluoroethylene (PTFE), while it is still in a flexible state and then annealing the membrane to “lock in” and strengthen the

Fig. 4 Porous structure of Celluloseacetate. (Courtesy of Sartorius AG.)

Fig. 5 PTFE membrane structure. (Courtesy of Sartorius AG.)

pores in the stretched membrane. The stretching process results into a distinctive membrane structure of PTFE nodes, which are interconnected by fibrils, (Fig. 5).

PTFE membranes are highly hydrophobic and, therefore, are used as air filters. Air filters have to be highly hydrophobic to avoid water blockage due to moisture or condensate, especially after steam sterilization of these filters. Water blockage could be detrimental, if the filter is, for example, used in a tank venting application to overcome condensation vacuum of a nonvacuum resistant tank. If the filter would not allow a free flow of air into the tank, it may implode. Therefore, vent filters for this application have to be chosen and sized with care. PTFE membranes are also highly mechanical and thermal resistant, which is required, because such filters are used over several months, withstanding multiple steam-sterilization cycles. Especially in large-scale fermentation, these filters are used over several months, avoiding unwanted infections of the fermenter's or bioreactor's cell line.

Finally, track-etched MF membranes are made from polymers, such as polycarbonate and polyester, wherein electrons are bombarded onto the polymeric surface. This bombardment results in "sensitized tracks," where chemical bonds in the polymeric backbone are broken. Subsequently, the irradiated film is placed in an etching bath (such as a basic solution), in which the damaged polymer in the tracks is preferentially etched from the film, thereby forming cylindrical pores. The residence time in the irradiator determines pore density, and residence time in the etching bath determines pore size. Membranes made by this process generally have cylindrical pores with very narrow pore-size distribution, albeit with low overall porosity. Furthermore, there always is the risk of a double hit, i.e., the etched pore becomes wider and could result in particulate penetration. Such filter membranes are often used in the electronic industry to filter high-purity water.

Table 1 lists the different membrane polymers available and the advantages and disadvantages, which depend on the properties of the polymer. The table shows that there is no such thing as a membrane polymer for every application. Therefore, filter membranes and the filter performance have to be tested before choosing the appropriate filter element.

FILTER CONSTRUCTION

Filters are available in several constructions, effective filtration areas, and configurations. Depending on the

individual process, the filter construction and setup will be chosen to fit its purpose best. Most commonly used for RO filters are tubular devices, so-called spiral wound modules due to the spiral configuration of the membrane within the support construction of such device. UF systems can be found as a spiral wound module, a hollow fiber, or a cassette device. The choice of the individual construction depends on the requirements and purposes towards the UF device. Similar to the different membrane materials, UF device construction has to be evaluated in the specific applications to reach an optimal functioning of the unit. Microfilters and depth filters can be lenticular modules or sheets but are mainly cylindrical filter elements of various sizes and filtration areas, from very small scale of 300 cm² to large scale devices of 36 m². A 10-inch high cylindrical filter element can be seen in Fig. 6.

These filter elements are installed into stainless steel filter housings by pushing the double O-ring cartridge adapter into the housing base plate recess. The filter housing is then assembled and connected, and the filter is flushed with water and steam-sterilized, either by in-line steaming or autoclaved. If filter housings are not available or not preferred, disposable filters can be used. The filter element is welded into a plastic housing, usually Polypropylene, and after every filtration process, discarded. The advantage of such a disposable filter device is the reduced cleaning validation effort, and the user does not come in contact with the filtered product. Such disposable filters can be autoclaved, but not in-line steam-sterilized, due to the pressure-temperature ratio of the housing polymer. Most often, such disposable filters are used for scale-up filtration tests, due to the ease of use and the availability of a band of effective filtration areas.

FILTER VALIDATION

Pharmaceutical processes are validated processes to assure a reproducible product within set specifications. Equally important is the validation of the filters used within the process, especially the sterilizing grade filters, which, often enough, are used before filling or the final processing of the drug product. In its Guideline on General Principles of Process Validation, 1985 (8), and Guideline on Sterile Drug Products Produced by Aseptic Processing, 1987 (2), the FDA makes plain that the validation of sterile processes is required by the manufacturers of sterile products.

Sterilizing grade filters are determined by the bacteria challenge test. This test is performed under strict

Table 1 Advantages and disadvantages of various membrane polymers

Membrane material	Advantages	Disadvantages
Cellulose acetate	Very low nonspecific adsorption (nonfouling) High flow rates and total throughputs	Limited pH compatibility Not dry autoclavable
Cellulose nitrate (nitrocellulose)	Good flow rate and total throughputs	High nonspecific adsorption Limited pH compatibility Not dry autoclavable
Regenerated cellulose	Very low nonspecific adsorption (nonfouling) Very high flow rates and total throughputs	Limited pH compatibility Not dry autoclavable
Modified regenerated cellulose	Very low nonspecific adsorption (nonfouling) Moderate flow rates and total throughputs, especially with difficult to filter solutions Broad pH compatibility	Ultrafilters not dry autoclavable
Nylon 66	Good solvent compatibility Good mechanical strength Broad pH compatibility Dry autoclavable	High nonspecific protein adsorption Low hot-water resistance Moderate flow rate and total throughput
Polycarbonate	Good chemical compatibility	Moderate flow rates Low total throughputs Difficult to produce
Polyethersulfone	High flow rates and total throughputs Broad pH compatibility	Moderate-to-low nonspecific adsorption, depending on surface modifications. Limited solvent compatibility

(Continued)

Table 1 Advantages and disadvantages of various membrane polymers (*Continued*)

Membrane material	Advantages	Disadvantages
Polypropylene	Excellent chemical resistance High mechanical resistance	Hydrophobic material High nonspecific adsorption due to hydrophobic interactions
Polysulfone	High flow rates and total throughputs Broad pH compatibility	Moderate-to-high nonspecific adsorption Limited solvent compatibility
Polytetrafluoro-ethylene	Excellent chemical resistance High mechanical resistance	Hydrophobic material High nonspecific adsorption due to hydrophobic interactions High-cost filter material
Polyvinylidene-difluoride	Low nonspecific adsorption Dry autoclavable Good solvent compatibility	Moderate flow rate and total throughput Hydrophobic base, made hydrophilic by chemical surface treatment; may lose hydrophilic modification due to chemical attack High-cost filter material

Fig. 6 10-inch standard filter element with pleated membrane and protection fleeces. (Courtesy of Sartorius AG.)

parameters and a defined solution (ASTM F 838-83) (3). In any case, the FDA nowadays also requires evidence that the sterilizing grade filter will create a sterile filtration, no matter the process, fluid or bioburden, found (6, 9). This means that bacteria challenge tests have to be performed with the actual drug product, bioburden, if different or known to be smaller than *B. diminuta* and the process parameters. The reason for the requirement of a product bacteria challenge test is threefold. First, the influence of the product and process parameters to the microorganism has to be tested. There may be cases of either shrinkage of organisms due to a higher osmolarity of the product or prolonged processing times. Second, the filter's compatibility with the product and the parameters has to be tested. The filter should not show any sign of degradation due to the product filtered. Additionally, rest assurance is required that the filter used will withstand the process parameters; e.g., pressure pulses, if happening, should not influence the filter's performance. Third, there are two

separation mechanisms involved in liquid filtration: sieve retention and retention by adsorptive sequestration (1, 8, 10–12). In sieve retention, the smallest particle or organism size is retained by the biggest pore within the membrane structure. The contaminant will be retained, no matter the process parameters. This is the ideal. Retention by adsorptive sequestration depends on the filtration conditions. Contaminants smaller than the actual pore size penetrate such and may be captured by adsorptive attachment to the pore wall. This effect is enhanced using highly adsorptive filter materials, for example, Glassfibre as a prefilter or Polyamide as a membrane. Nevertheless, certain liquid properties can minimize the adsorptive effect, which could mean penetration of organisms. Whether the fluid has such properties and will lower the effect of adsorptive sequestration and may eventually cause penetration has to be evaluated in specific product bacteria challenge tests. Table 2 shows the advantages and disadvantage of both separation mechanisms.

Before performing a product bacteria challenge test, it has to be assured that the liquid product does not have any detrimental, bactericidal or bacteriostatic, effects on the challenge organisms. This is done utilizing viability tests. The organism is inoculated into the product to be filtered at a certain bioburden level. At specified times, the log value of this bioburden is tested. If the bioburden is reduced due to the fluid properties, a different bacteria challenge test mode becomes applicable (7). If the reduction is a slow process, the challenge test will be performed with a higher bioburden, bearing in mind that the challenge level has to reach 10^7 per square centimeter at the end of the processing time. If the mortality rate is too high, the toxic substance is either removed or product properties are changed. This challenge fluid is called a placebo. Another methodology would circulate the fluid product through the filter at the specific process parameters as long as the actual processing time would be. Afterwards, the filter is flushed extensively with water and the challenge test, as described in ASTM F838-38, performed. Nevertheless, such a challenge test procedure would be more or less a filter compatibility test.

Besides the product bacteria challenge test, tests of extractable substances or particulate releases have to be performed (7, 8, 13). Extractable measurements and the resulting data are available from filter manufacturers for the individual filters. Nevertheless, depending on the process conditions and the solvents used, explicit extractable tests have to be performed. These tests are commonly done only with the solvent used with the drug product but not with the drug ingredients themselves, because the drug product usually covers any extractables during measurement. Such

Table 2 Advantages and disadvantages of separation mechanisms

Retention mechanism	Advantages	Disadvantages
Sieve retention	Reliable at worst case product properties Reliable separation even at high flows and pressure conditions Blockage, i.e., exhaustion, can be determined No unspecific adsorption, minimal loss of desired product, and little adsorptive fouling	Retentive only at the specific pore size rating
Adsorptive sequestration	It is possible to retain particles smaller than the filter's indicated pore size Separation of colloidal substances is possible In some case, pyrogens can be removed	Highly influenced by product specific properties Separated particles can be shed by varying process conditions Saturation of the active sites cannot be determined, no warning Unspecific adsorption will result in product losses and fouling Lower reliability in terms of absolute separation

tests are conducted by the validation services of the filter manufacturers using sophisticated separation and detection methodologies, as GC-MS, FTIR, and RP-HPLC. These methodologies are required, due to the fact that the individual components possibly released from the filter have to be identified and quantified. Elaborate studies, performed by filter manufacturers, showed that there is neither a release of high quantities of extractables (the range is ppb to max ppm per 10-inch element) nor have toxic substances been found (13).

Particulates are critical in sterile filtration, specifically of injectables. The USP 24 (*United States Pharmacopoeia*) and BP (*British Pharmacopoeia*) quote specific limits of particulate level contaminations for defined particle sizes. These limits have to be kept and, therefore, the particulate release of sterilizing grade filters has to meet these requirements. Filters are routinely tested by evaluating the filtrate with laser particle counters. Such tests are also performed with the actual product under process conditions to prove that the product, but especially process conditions, do not result in an increased level of particulates within the filtrate.

Additionally, with certain products, loss of yield or product ingredients due to adsorption shall be determined (14, 15). For example, preservatives, like benzalkoniumchloride or chlorhexadine, can be adsorbed by specific filter membranes. Such membranes need to be saturated by the preservative to avoid preservative

loss within the actual product. This preservative loss, e.g., in contact lens solutions, can be detrimental, due to long-term use of such solutions. Similarly, problematic would be the adsorption of required proteins within a biological solution. To optimize the yield of such proteins within an application, adsorption trials have to be performed to find the optimal membrane material and filter construction.

Cases that use the actual product as a wetting agent to perform integrity tests require the evaluation of product integrity test limits (7, 17). The product can have an influence on the measured integrity test values due to surface tension, or solubility. A lower surface tension, for example, would shift the bubble point value to a lower pressure and could result in a false negative test. The solubility of gas into the product could be reduced, which could result in false positive diffusive flow tests. Therefore, a correlation of the product as a wetting agent to the, water wet values has to be done, according to standards set by the manufacturer of the filter. This correlation is carried out by using a minimum of three filters of three filter lots. Depending on the product and its variability, one or three product lots are used to perform the correlation. The accuracy of such a correlation is enhanced by automatic integrity test machines. These test machines measure with highest accuracy and sensitivity and do not rely on human judgement, as with a manual test (7). Multipoint

diffusion testing offers the ability to test the filter's performance and, especially, to plot the entire diffusive flow graph through the bubble point. The individual graphs for a water-wet integrity test can now be compared to the product wet test and a possible shift evaluated. Furthermore, the multipoint diffusion test enables the establishment of an improved statistical base to determine the product wet versus water-wet limits (16, 17).

FILTER INTEGRITY TESTING

Sterilizing grade filters require testing to assure the filters are integral and fulfill their purpose. Such filter tests are called integrity tests and are performed before and after the filtration process. Sterilizing grade filtration would not be admitted to a process if the filter would not be integrity tested in the course of the process. This fact is also established in several guidelines, recommending the use of integrity testing, pre- and post-filtration. This is not only valid for liquid but also for air filters.

Examples of such guidelines are:

1. *FDA Guideline on Sterile Drug Products Produced by Aseptic Processing* (1987): Normally, integrity testing of the filter is performed after the filter unit is assembled and prior to use. More importantly however, such testing should be conducted after the filter is used in order to detect any filter leaks or perforations that may have occurred during filtration.
2. *The Guide to Inspections of High Purity Water Systems, Guide to Inspections of Lyophilization of Parenterals*, and also the CGMP document 212.721 Filters state the following:
 - a. The integrity of all air filters shall be verified upon installation and maintained throughout use. A written testing program adequate to monitor integrity of filters shall be established and followed. Results shall be recorded and maintained as specified in 212.83.
 - b. Solution filters shall be sterilized and installed aseptically. The integrity of solution filters shall be verified by an appropriate test, both prior to any large-volume parenteral solution filtering operation and at the conclusion of such operation before the filters are discarded. If the filter assembly fails the test at the conclusion of the filtering operation, all materials filtered through it during that filtering operation should be rejected. Rejected materials may be refiltered using filters

whose integrity has been verified provided that the additional time required for refiltration does not result in a total process time that exceeds the limitations specified in 212.111. Results of each test shall be recorded and maintained as required in 212.188(a)

3. ISO 13408-1 *First Edition, 1998-08-1, Aseptic Processing of Health Care Products*, Part 1: General requirements: Section 17.11.1 Investigation, m. pre- and post-filter integrity test data, and/or filter housing assembly:

20.3.1. A validated physical integrity test of a process filter shall be conducted after use without disturbing the filter housing assembly. Filter manufacturer's testing instructions or recommendations may be used as a basis for a validated method. Physical integrity testing of a process filter should be conducted before use where process conditions permit. "Diffusive Flow," "Pressure Hold," and "Bubble Point" are acceptable physical integrity tests.

20.3.2. The ability of the filter or housing to maintain integrity in response to sterilization and gas or liquid flow (including pressure surges and flow variations) shall be determined.

4. USP 23, 1995, P. 1979. *Guide to Good Pharmaceutical Manufacturing Practice* (Orange Guide, U.K., 1983):

PDA (Parenteral Drug Association), Technical Report No. 26, *Sterilizing Filtration of Liquids* (March 1998):

Integrity tests, such as the diffusive flow, pressure hold, bubble point, or water intrusion tests, are nondestructive tests, which are correlated to the destructive bacteria challenge test with $10^7/\text{cm}^2$ B. diminuta (1, 8). Derived from these challenge tests, specific integrity test limits are established, which are described and documented within the filter manufacturers' literature. The limits are water-based; i.e., the integrity test correlations are performed using water as a wetting medium. If a different wetting fluid, such as a filter or membrane configuration, is used, the integrity test limits may vary. Integrity test measurements depend on the surface area of the filter, the polymer of the membrane, the wetting fluid, the pore size of the membrane, and the gas used to perform the test. Wetting fluids may have different surface tensions, which can depress or elevate the bubble point pressure. The use of different test gases may elevate the diffusive gas flow. Therefore, appropriate filter validation has to be

established to determine the appropriate integrity test limits for the individual process.

Bubble Point Test

Microporous membranes will fill their pores with wetting fluids by imbibing that fluid in accordance with the laws of capillary rise. The retained fluid can be forced from the filter pores by air pressure applied from the upstream side. The pressure is increased gradually in increments. At a certain pressure level, liquid will be forced first from the set of largest pores, in keeping with the inverse relationship of the applied air pressure P and the diameter of the pore, d , described in the bubble point equation:

$$P = \frac{4\gamma \cos \theta}{d} \quad (1)$$

where γ is the surface tension of the fluid, θ is the wetting angle, P is the upstream pressure at which the largest pore will be freed of liquid, and d is the diameter of the largest pore.

When the wetting fluid is expelled from the largest pore, a bulk gas flow will be detected on the downstream side of the filter system (Fig. 7). The bubble point measurement determines the pore size of the filter membrane, i.e., the larger the pore the lower the bubble point pressure. Therefore, filter manufacturers specify the

bubble point limits as the minimum allowable bubble point. During an integrity test, the bubble point test has to exceed the set minimum bubble point.

Diffusion Test

A completely wetted filter membrane provides a liquid layer across which, when a differential pressure is applied, the diffusive airflow occurs in accordance with Fick's law of diffusion (Fig. 8). This pressure is called test pressure and commonly specified at 80% of the bubble point pressure. In an experimental elucidation of the factors involved in the process, Reti (18) simplified the integrated form of Fick's law to read as follows:

$$N = \frac{DH(p_1 - p_2)}{L} \cdot \rho$$

where N is the permeation rate (moles of gas per unit time), D is the diffusivity of the gas in the liquid, H is the solubility coefficient of the gas, L is the thickness of liquid in the membrane (equal to the membrane thickness if the membrane pores are completely filled with liquid), P ($p_1 - p_2$) is the differential pressure, and ρ is the void volume of the membrane, its membrane porosity, commonly around 80%.

The size of pores only enter indirectly into the equation; in their combination, they comprise L , the thickness of the

Fig. 7 Manual bubble point test set-up. (Reprinted from Technical Report No. 26, Sterilizing Filtration of Liquids © 1998 by PDA.)

Fig. 8 Manual diffusive flow test set-up. (Reprinted from Technical Report No. 26, Sterilizing Filtration of Liquids © 1998 by PDA.)

liquid layer, the membrane being some 80% porous. The critical measurement of a flaw is the thickness of the liquid layer. Therefore, a flaw or an oversized pore would be measured by the thinning of the liquid layer due to the elevated test pressure on the upstream side. The pore or defect may not be large enough that the bubble point comes into effect, but the test pressure thins the liquid layer enough to result into an elevated gas flow. Therefore, filter manufacturers specify the diffusive flow integrity test limits as maximum allowable diffusion value. The larger the flaw or a combination of flaw, the higher the diffusive flow.

Pressure Hold Test

The pressure hold test is a variant of the diffusive airflow test (19). The test set-up is arranged as in the diffusion test except that when the stipulated applied pressure is reached, the pressure source is valved off (Fig. 9). The decay of pressure within the holder is then observed as a function of time, using a precision pressure gauge or pressure transducer.

The decrease in pressure can come from two sources: 1) the diffusive loss across the wetted filter. Because the upstream side pressure in the holder is constant, it decreases progressively as all the while diffusion takes

place through the wetted membrane; and 2) the source of pressure decay could be a leak of the filter system set-up.

An important influence on the measurement of the pressure hold test is the upstream air volume within the filter system. This volume has to be determined first to specify the maximum allowable pressure drop value. The larger the upstream volume, the lower will the pressure drop be. The smaller the upstream volume, the larger the pressure drop. This also means an increase in the sensitivity of the test, and also an increase of temperature influences, if changes occur. Filter manufacturers specify maximum allowable pressure drop values.

Water Intrusion Test

The water intrusion test is used for hydrophobic vent and air membrane filters only (20–23). The upstream side of the hydrophobic filter cartridge housing is flooded with water. The water will not flow through the hydrophobic membrane. Air or nitrogen gas pressure is then applied to the upstream side of the filter housing above the water level to a defined test pressure. This is done by way of an automatic integrity tester. A period of pressure stabilization takes place over time frame, by the filter manufacturer's recommendation, during which the

Fig. 9 Manual pressure-hold test set-up. (Reprinted from Technical Report No. 26, Sterilizing Filtration of Liquids © 1998 by PDA.)

cartridge pleats adjust their positions under imposed pressures. After the pressure drop thus occasioned stabilizes, the test time starts, and any further pressure drop in the upstream pressurized gas volume, as measured by the automatic tester, signifies a beginning of water intrusion into the largest (hydrophobic) pores, water being incompressible. The automated integrity tester is sensitive enough to detect the pressure drop. This measured pressure drop is converted into a measured intrusion value, which is compared to a set intrusion limit, which has been correlated to the bacteria challenge test. As with the diffusive flow test, filter manufacturers specify a maximum allowable water intrusion value. Above this value, a hydrophobic membrane filter is classified as nonintegral.

Film Coating of Oral Solid Dosage Forms

Linda A. Felton

*University of New Mexico College of Pharmacy, Albuquerque,
New Mexico, U.S.A.*

INTRODUCTION

Polymeric materials have been used to coat pharmaceutical solid dosage forms for decorative, protective, and functional purposes. These thin polymeric film coatings may improve the esthetic appearance and provide easy identification of drug products. Polymer coatings may be used to enhance the chemical stability of the drug in a dosage form by providing a physical barrier to environmental storage conditions.^[1,2] Application of a polymeric film may also improve the physical stability of solid dosage forms by increasing the strength and fracture resistance of the solid.^[3] Reactive components within a single dosage form may be separated using polymeric film coatings. Taste and odor masking of drugs may also be accomplished with the use of polymeric film coatings.^[4] One of the most common reasons for the application of polymeric coatings is to alter the release characteristics of drugs.^[5–7] This article discusses formulation development, processing, and testing of polymeric films and film-coated products.

FUNDAMENTALS OF FILM FORMATION

In the pharmaceutical industry, polymeric films are generally applied to solid dosage forms using a spray-atomization technique. The polymer is dissolved or dispersed in aqueous or organic solvents prior to spraying. The solid cores are often preheated in the coating equipment prior to initiation of the coating process. This prewarming stage is especially important in the coating of soft gelatin capsules.^[8,9] The coating solution or dispersion is atomized with air into small droplets, which are then delivered to the surface of the substrate. Upon contact, the atomized droplets spread across the substrate surface. The solvent may penetrate into the core, causing surface dissolution and physical mixing at the film–tablet interface.^[10] As the solvent begins to evaporate, the polymer particles densely pack on the surface of the solid. A schematic of the film formation process for an aqueous polymeric dispersion is shown in Fig. 1.

Upon further solvent evaporation, the particles flow together due to the cohesive forces between the polymer spheres, a process known as coalescence. Heat is generally added to the coating equipment to facilitate solvent evaporation and film formation.^[11]

Immediately following the completion of the coating process, coated solids are generally stored at temperatures above the glass transition temperature of the polymer to further promote coalescence of the film^[6] and ensure a homogeneous distribution of the plasticizer.^[12] During this postcoating storage or curing stage, the microstructure of the polymer is altered,^[13] and the mechanical, adhesive,^[14] and drug release properties^[15,16] of the film are correspondingly affected. The time required to obtain a stable film without further aging effects is dependent on a number of factors, including the type and concentration of plasticizer,^[17,18] the bed temperature used during coating,^[16] and the storage conditions.^[11] Fig. 2 shows the influence of curing on theophylline release from pellets coated with an acrylic polymer.^[15] Drug release rates slowed during storage at elevated temperatures and higher concentrations of the plasticizer in the coating reduced the time necessary for complete film coalescence.

While the majority of published research has shown that curing slows drug release, Bodmeier and Paeratakul^[13] found that curing could enhance or retard drug release, depending on curing conditions, plasticizer concentration, and the physicochemical properties of the drug. In that study, chlorpheniramine maleate was found to have a low affinity for the ethyl cellulose polymer and curing slowed drug release. In contrast, ibuprofen was found to have a high solubility in ethyl cellulose and longer curing times resulted in faster drug release. Drug crystals were found on the surface of the coated pellets following curing and the researchers attributed these findings to diffusion of the drug into the film. A subcoat or intermediate seal coat was suggested to minimize interaction between the drug and the cellulosic polymer.

Fig. 1 Schematic representation of the film formation process for an aqueous polymeric dispersion: (A) atomization of the polymeric dispersion; (B) deposition of the polymeric dispersion on the substrate surface; (C) packing of the polymer spheres with water filling the void spaces; (D) formation of continuous polymeric film.

COATING EQUIPMENT

There are three types of coating equipment used to apply polymeric materials: conventional coating pans, perforated coating pans, and fluidized beds. More detailed discussions of the various coating equipments may be found elsewhere.^[19–21] The conventional coating pan system consists of a round coating pan that rotates on an inclined axis. Tablets in the coating pan tumble due to pan rotation. Heat is blown across the surface of the tumbling tablets and exhaust air is withdrawn. The conventional coating pan was originally used in the sugar coating process, where syrups were ladled onto the substrates. Aqueous polymeric film coating, however, requires more rapid solvent evaporation and the drying efficiency of conventional coating pans was improved by adding perforations. These perforations allow air to be forced through the tablet bed. A schematic of a perforated coating pan is shown in Fig. 3. As with conventional coating systems, pan rotation causes the solid cores to continually

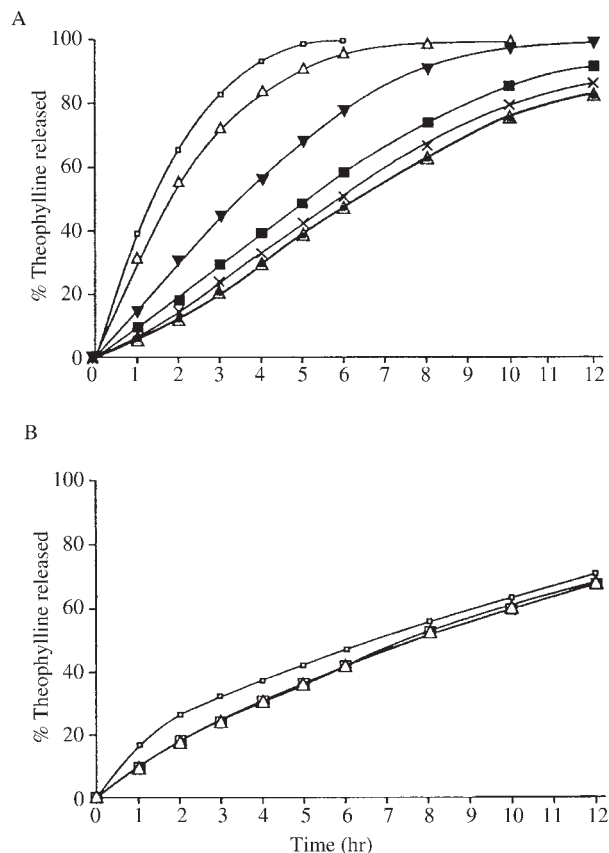

Fig. 2 Change in drug release from theophylline pellets coated with Eudragit® RS 30 D containing 5% Pharmacoat® 606 and either (A) 20% triethyl citrate or (B) 30% triethyl citrate after storage at 40 °C/50% relative humidity. move during the coating process. The application zone is the area in the pan where the atomized polymer is sprayed onto the substrate surface. Tablets must make multiple passes through the application zone to form the film. Baffles in the perforated coating pans contribute to the tumbling action of the tablets and facilitate uniform film coverage.

In contrast to the coating pans, small particles such as beads, pellets, granules, and powders are generally coated using the fluidized bed or air suspension method, which utilizes a carrier gas to keep the cores in motion. The high air current makes this technique more efficient at water removal.^[22] The bottom spray technique is one of the most common fluidized bed application methods and a schematic of this process is shown in Fig. 4A. A perforated distribution base plate allows sufficient air into the product container to force the particles up into a cylindrical

Film Coating of Oral Solid Dosage Forms

3

Fig. 3 Schematic of a perforated coating pan apparatus. (From Ref. 19.)

or slightly conical coating chamber, known as a Wurster insert. These inserts have been recently improved to keep the particles away from the spray nozzle until the spray pattern is fully developed.^[23] The bottom spray method provides ideal conditions for complete film coalescence.^[24] The particle size of the pellets, however, has been shown to influence fluidization patterns, which may ultimately affect the thickness of the film coating.^[25]

Two additional spray techniques have been used in fluidized bed coating. As shown in Fig. 4B, the top spray method, also known as the granulator mode, sprays the polymeric material countercurrently into the fluidizing particles. Because the coatings produced are not uniform in thickness, the top spray technique is suitable for taste

and odor masking, where drug release is not dependent on film thickness.^[19] The rotary or tangential spray technique, shown in Fig. 4C, uses a rotating disk to add a centrifugal force to fluidization and gravity. While films produced using this method are similar to those created with the Wurster system,^[23] the drying efficiency is improved and higher spray rates may be employed. Using the tangential spray system, film thickness has been shown to be independent of the particle size of the cores.^[25] One of the drawbacks of this application technique, however, is a greater potential for adhesion of particles to the upper walls of the product chamber.

Irrespective of the type of coating equipment used, polymeric solutions and dispersions are generally applied using a spray-atomization technique and two types of spray nozzles are employed. With pneumatic nozzles, high-pressure air is passed across the fluid stream as it exits the nozzle opening. In contrast, hydraulic nozzles rely on the fluid being pumped at relatively high pressures through a small opening. One of the advantages of pneumatic nozzles is that the atomized droplet size can be controlled independently of the polymer flow rate, whereas changing the spray rate of a hydraulic nozzle without adjusting the nozzle will result in changes in the atomization spray pattern.^[19]

A variety of pumps may be used to deliver the coating material to the spray nozzle. The peristaltic pump is ideal for delivering latex and pseudolatex polymeric dispersions that may coagulate at high pressure. This pump is the most commonly used and is also the easiest to clean. To control the delivery of the liquid polymeric material more precisely, a gear pump may be employed. Problems with undissolved solids in the coating formulation, however, may arise due to the tight tolerances between the two gears. The gear pump is also more difficult to clean

Fig. 4 Schematic of a fluidized bed coating apparatus: (A) bottom spray with Wurster column insert; (B) top spray technique; (C) tangential spray technique. (From Ref. 25.)

compared to the peristaltic system. A piston pump utilizes both air and hydraulic systems. One of the advantages of the piston pump is that minor clogs in the nozzle may be easily cleared due to the pressure reserve. Polymeric materials, however, may coagulate due to the high pressures used and the piston system is quite difficult to clean.

To overcome problems associated with traditional coating processes, several novel coating methods have been proposed. Obara et al.^[26] demonstrated the “dry coating” technique, where the polymer powder is fed directly to the tablet or pellet bed with simultaneous spraying of a plasticizing agent. Although modifications may be necessary, this technique can be used in fluidized bed and perforated coating pan methods, as shown in Fig. 5A and B, respectively. This method uses no organic solvents or water. The researchers reported that processing times were dramatically reduced, although higher amounts of an enteric polymer were required for gastric resistance. An electrostatic coating process has also been described.^[27]

FILM COATING MATERIALS

Film Formers

Materials used to coat pharmaceutical products are primarily based on acrylic and cellulosic polymers and

the aqueous solubility characteristics of these compounds generally dictate their uses. Sustained release coatings are water-insoluble or swellable films through which the medicament slowly diffuses. Drug products coated with these polymers are administered less frequently and the high peak plasma concentrations associated with side effects may be reduced or eliminated. Common sustained release polymers commercially available include ethyl cellulose and water-insoluble polymethacrylates. These polymeric materials may also be used as binders in sustained release matrix tablets and in other novel drug delivery systems. In contrast, water-soluble polymers, including hydroxypropyl cellulose, hydroxypropyl methylcellulose, sodium carboxymethylcellulose, and polyvinyl pyrrolidone, are often used for rapidly disintegrating film-coated tablets. These materials have also been added to the water-insoluble polymers to accelerate drug release from sustained release films.^[17,28]

Enteric film coatings exhibit pH-dependent solubility and have been used to protect drugs from degradation in the stomach.^[29] Enteric coatings have also been employed to decrease the incidence of gastric irritation from drugs^[30] or target drug delivery to the small intestines. In the low pH of the stomach, mixed acid and acid ester functional groups on the enteric polymers are unionized, and therefore, insoluble. As the pH increases in the intestinal tract, these functional groups ionize and the polymer becomes soluble. Thus, an enteric polymeric film allows the coated solid to pass through the stomach intact and release the medication in the small intestines. Common enteric polymers commercially available include cellulose acetate phthalate, hydroxypropyl methylcellulose phthalate, hydroxypropyl methylcellulose acetate succinate, polyvinyl acetate phthalate, and several methacrylic acid copolymers.

Solvents

Many solvent systems have been used to disperse or dissolve polymers for pharmaceutical film coating purposes. The primary criteria for the selection of a solvent for a particular polymer system include solvency, volatility, toxicity, and pollution control. The most superior films, showing the greatest combined strength of cohesiveness, have been reported when the coating solution solvation and polymer chain extension are at a maximum.^[31] Film coating technology, however, has shifted toward aqueous-based systems for environmental and economic reasons and the majority of polymeric materials used today are applied as aqueous-based solutions and dispersions. With aqueous-based systems,

Fig. 5 Schematic of the “dry coating” method: (A) fluidized bed apparatus; (B) pan coating apparatus. (From Ref. 26.)

the risk of explosion is diminished, costs of disposing of the solvents are reduced, and concerns of potential toxicities due to residual solvents within the film are eliminated. Many commercial polymeric systems are available as aqueous latex and pseudolatex dispersions, where colloidal polymer particles are suspended in water. Latexes are obtained by emulsion polymerization, whereas emulsification of polymeric solutions is used to produce pseudolatex dispersions. Pseudolatexes may also be prepared from suspensions of spray-dried or mechanically milled solid polymer particles. The viscosity of these latex and pseudolatex dispersions is independent of the molecular weight of the polymer and only slight increases in viscosity occur with increased polymer concentration.^[32]

Plasticizers

Many pharmaceutical polymers exhibit brittle properties and require the addition of a plasticizing agent to obtain an effective coating, free of cracks, edging, or splitting. Plasticizers function by weakening the intermolecular attractions between the polymer chains and generally cause a decrease in the tensile strength and the glass transition temperature and an increase in the flexibility of the films.^[33] Plasticizers are necessary components to reduce brittleness, improve flow, impart flexibility, and to increase toughness, strength, and tear resistance of the film.^[34] These plasticizers play a critical role in the performance of polymeric film coatings.^[15,35]

Plasticizers are generally nonvolatile, high boiling, nonseparating substances that, when added to polymers, change certain physical and mechanical properties of that material. Plasticizers used in a polymeric system should be miscible with the polymer and exhibit little tendency for migration, exudation, evaporation, or volatilization. Many compounds can be used to plasticize polymers, including water. Phthalate esters such as diethyl phthalate, sebacate esters such as dibutyl sebacate, and citrate esters such as triethyl citrate and tributyl citrate are commonly used as plasticizing agents. Various glycol derivatives including propylene glycol and polyethylene glycol have also been used to plasticize polymeric films. In addition, surfactants, preservatives, and other compounds have been shown to function as plasticizing agents in cellulosic and acrylic polymers.^[36,37]

To be effective, a plasticizer must partition from the solvent phase into the polymer phase and subsequently diffuse throughout the polymer to disrupt the intermolecular interactions.^[38] The rate and extent of this partitioning for an aqueous dispersion have been found to be dependent on the solubility of the plasticizer in water

and its affinity for the polymer phase. The partitioning of water-soluble plasticizers in an aqueous dispersion occurs rapidly, whereas significantly longer equilibration times are required for water-insoluble plasticizing agents.^[8,39] For aqueous-based dispersed systems, water-insoluble plasticizers should be emulsified first and then added to the polymer.^[40] Sufficient time must be allowed for plasticizer uptake into the polymer phase prior to the initiation of coating. If insufficient time for plasticizer partitioning is given, the unincorporated plasticizer droplets, as well as the plasticized polymer particles, will be sprayed onto the substrates during the coating process, resulting in uneven plasticizer distribution within the film, which could potentially cause changes in the polymer properties of the film over time. Siepmann et al.^[41] developed a plasticizer uptake model to predict the minimum stirring time necessary for complete partitioning of plasticizers into aqueous polymeric dispersions. A postcoating thermal treatment may help reduce or eliminate the plasticization time effects.^[18]

The effectiveness of a plasticizing agent is dependent, to a large extent, on the amount of plasticizer added to the film coating formulation and the extent of polymer–plasticizer interaction. Forces involved in polymer–plasticizer mixtures include hydrogen bonding, dipole–dipole, and dipole-induced dipole interactions, as well as dispersions forces. Many experimental methods to determine the extent of polymer–plasticizer interactions have been reported in the pharmaceutical literature, including torsional braid pendulum,^[42] vapor pressure depression,^[43] osmotic pressure,^[44] swelling tests,^[45] gas–liquid chromatography,^[46] viscometry,^[47] melting point depression,^[48] nuclear magnetic resonance,^[49] and Fourier transform infrared.^[50] The degree of plasticizer–polymer interactions has been extensively characterized using differential scanning calorimetry and the decrease in the glass transition temperature of the polymer with the addition of a plasticizing agent is a common measure of plasticizer effectiveness.^[33,51,52]

Other Additives

In addition to the polymer, plasticizer, and solvent, other water-soluble and water-insoluble compounds such as pigments, antiadherents, surfactants, and antifoaming agents may be added to coating formulations to improve the appearance of the final dosage form, to facilitate processing, and to reduce the tackiness of the films. Drugs have also been incorporated directly into film coating formulations.^[32,53] The volume concentration, size and size distribution, chemical properties and surface charge of the additives, and the extent of polymer–particle interaction

may significantly affect the mechanical, adhesive, and drug-release properties of the coatings.^[54–56] Several classes of commonly used film coating additives are discussed below.

Antiadherents

During coating, curing, and storage, many pharmaceutical film coatings become sticky and the coated particles may agglomerate. The degree of tackiness correlates with the minimum film forming temperature of the polymer and has been shown to increase with increasing plasticizer concentration.^[57] To reduce the stickiness of the film and minimize agglomeration of the coated substrates, antiadherent compounds are generally included in coating formulations and talc is one of the most common antiadherents used. However, the high levels of talc (up to 100% w/w, based on dry polymer weight) required to reduce the tackiness of the coating may result in clogging of the spray nozzle and particle sedimentation. Furthermore, talc is hydrophobic and the addition of talc to polymeric films has been shown to decrease water vapor permeability^[2] and the dissolution rate of drugs.^[58] Other studies, however, have shown that talc may increase dissolution, presumably by forming cracks in the coating.^[59] Talc has also been found to affect the mechanical, thermal, and adhesive properties of polymeric films.^[60,61] Glyceryl monostearate (GMS) has been used as an alternative to talc.^[62] Wesseling et al.^[57] showed that 5% GMS was as effective as 50% talc in reducing the tackiness of several acrylic polymeric films.

Colorants

Pigments used in pharmaceutical systems include aluminum lakes of water-soluble dyes, opacifiers such as titanium dioxide, and various inorganic materials including the iron oxides. Reports of color migration and stability issues have curtailed the use of water-soluble dyes in pharmaceutical products.^[63] Pigments have been employed to provide easy product identification and present a more pharmaceutically elegant dosage form. In addition, titanium dioxide and other opacifying agents have been incorporated into film coating formulations to improve the stability of light-sensitive drugs.^[1,64]

Incorporation of pigments into polymeric dispersions may result in incompatibilities, such as coagulation of the polymer or flocculation of the pigments.^[65] These instabilities are related to the size and surface charge of the components in the colloidal polymer formulation as well as the pH of the medium.^[66] Other excipients may be

added to the coating formulation to stabilize the polymeric dispersions.^[40] Sodium carboxymethylcellulose, for example, has been used at a concentration of approximately 6% (w/w, based on dry polymer weight) to stabilize pigmented acrylic dispersions.^[67] The polymer chains of this anionic cellulose ether lead to sterical stabilization of the pigment and prevent flocculation by increasing the viscosity of the mixture. Other approaches to stabilize aqueous polymeric dispersions have also been suggested.^[68]

Pigments differ significantly in their physical properties, including density, particle shape, particle size, and morphology, and these differences contribute to the complex relationship with aqueous film coatings. The size, shape, surface chemistry, and concentration of the pigments have been shown to affect polymer properties. Felton and McGinity,^[69] for example, found an inverse relationship between the particle size of the pigment and film–tablet adhesion. These researchers theorized that larger particles disrupt the interfacial bonding between the polymer and the surface of the tablet to a greater extent than the smaller particles. In another study, Rowe^[70] attributed the increased modulus of elasticity of polymeric films containing colorants to the shape of the pigment particle and to the extent of particle–polymer interaction. Maul and Schmidt^[71] investigated the effects of several pigments of similar size but differing in surface polarity on drug release. Fig. 6 shows that pigments with polar surfaces (such as titanium dioxide, iron oxide, and mica) produced films that were less permeable than when the hydrophobic talc was incorporated into the coating. Other studies have shown that the addition of titanium dioxide to acrylic and cellulosic films increases water vapor permeability^[2,72] and enhances polymer adhesion.^[69,73]

Fig. 6 Influence of surface chemistry of pigments on theophylline release from pellets coated with Eudragit® RS 30 D containing dibutyl phthalate as a plasticizer. (▼) Titanium dioxide as fine platelets; (■) mica; (×) talc; (○) red iron oxide fine platelets. (From Ref. 71.)

Film Coating of Oral Solid Dosage Forms

Surfactants

Surfactants have been added to coating formulations to improve substrate wettability,^[74] facilitate spreading of the polymeric material on the surface of the substrate,^[34] and homogenize the coating mixtures.^[75] Various polymer properties may be affected by the addition of surfactants to polymeric film coatings. Lindholm et al.^[76] for example, showed faster drug release rates occurred as the concentration of polysorbate 20, a hydrophilic nonionic surfactant, was increased in ethyl cellulose films. These researchers suggested that the surfactant leached from the coating during dissolution, creating pores in the film through which the drug diffused.

EVALUATION OF POLYMERIC FILMS

Determination of the drug release or dissolution properties of solid dosage forms is probably the most common test performed on pharmaceutical systems and methods for quantifying drug release are discussed elsewhere.^[77] For film-coated drug products, the polymer, film thickness, and plasticizer type and concentration have been shown to influence dissolution.^[15,78,79] The addition of soluble and insoluble excipients in the film coating formulation,^[80,81] processing parameters used during coating,^[16,82] post-coating drying,^[13,18] and storage conditions^[83] have also been shown to affect drug release.

The drug release characteristics and long-term stability of coated products may be predicted by evaluating isolated free films for permeability and mechanical strength. Methods commonly used to prepare isolated films include casting and spraying techniques. With the casting method, the polymeric solution or dispersion is cast onto a smooth surface of Teflon[®] or aluminum and the solvent is slowly evaporated. Use of insoluble excipients in the film coating formulation, however, may result in two different film surfaces being formed as the solvent is evaporated. Free films may also be prepared using an atomization spray process and a schematic of the apparatus is shown in Fig. 7. This spray-atomization technique is similar to processes used to coat pharmaceutical solids. The spray box consists of a rotating drum covered with a nonstick material that is encased in a hot box and the polymeric material is sprayed onto the rotating drum.^[84] Films prepared from aqueous polymeric dispersions using the spray method are generally more uniform and exhibit more consistent and reproducible mechanical properties than films prepared by the casting technique.^[85]

Fig. 7 Schematic of a spray box apparatus.

Water Vapor Permeability

Polymeric films have been used as barriers to protect moisture-sensitive drugs from atmospheric water and improve the stability of drugs that degrade by hydrolytic mechanisms.^[86] The water vapor permeability coefficient is used to evaluate the effectiveness of a particular film coating as a barrier to water. Water vapor permeability is commonly evaluated using isolated free films to construct water vapor transmission cells.^[53,87] A schematic of the apparatus is shown in Fig. 8.^[88] A water vapor transmission cell consists of a glass cylinder containing a saturated salt solution to produce a specific internal vapor pressure. The cylinder is then sealed with the polymeric film. Rubber rings and aluminum caps are often used to prevent water vapor egress through any areas other than the film. The transmission cells are placed in a humidity-controlled chamber and weighed periodically over a specified time period. These water vapor transmission cells rely on a vapor pressure gradient to achieve a linear weight gain. From the daily weight gains, the water vapor permeability constant can be calculated using Eq. 1:

$$P_{\text{erm}} = \frac{WL}{A \Delta P} \quad (1)$$

Fig. 8 Schematic of a water vapor transmission cell. (From Ref. 88.)

where P_{erm} is the moisture permeability constant, W is the amount of moisture transmitted per unit time, L is the thickness of the film, A is the area of the film exposed, and ΔP is the vapor pressure gradient. A method to determine water vapor permeation of applied films has also been reported.^[31]

Water vapor permeation has been shown to be dependent on the film composition,^[31,89] additives in the film,^[72] and the solvent system in which the polymer is dissolved or dispersed.^[2] A number of researchers have investigated the effects of plasticizers in coating formulations on the permeability of polymeric films.^[51,84,90] Water vapors have been shown to permeate more rapidly through films containing hydrophilic plasticizers,^[2] whereas the inclusion of a hydrophobic plasticizer in the coating has been found to exert no significant effects on water vapor permeability.^[91]

Thermal Analysis

Thermal analysis is a term used to describe a number of analytical experimental techniques that investigate polymer properties as a function of temperature. Some of the properties that can be determined include enthalpy, mass, melting temperature, heat of fusion, and the glass transition temperature. Hatakeyama and Quinn^[92] provide an excellent description of thermoanalytical techniques.

The glass transition temperature (T_g) is probably the most common physical property determined for amorphous polymeric materials. At temperatures below the T_g of the polymer, the material generally behaves as a hard and brittle glass, whereas the behavior of the polymer changes to soft and elastic at temperatures above the T_g . The degree of excipient–polymer interactions has been extensively characterized using differential scanning calorimetry. The effectiveness of a plasticizer in a film coating formulation has been related to its ability to decrease the T_g of the polymer.^[15,51,52] Table 1 shows the T_g of an acrylic polymer plasticized with several citrate esters.^[93] The addition of 10% plasticizer in the film coating produced a significant decrease in the T_g of the polymer for all compounds studied and higher concentrations of the plasticizer further lowered the T_g of the film. These data demonstrate that the citrates effectively plasticized the acrylic polymer.^[33] In contrast to plasticizing agents, other additives in film coating formulations, such as talc, titanium dioxide, and lactose, may increase the T_g of the film^[69,94] due to a restriction in the mobility of the polymer chains or a rise in the crystallinity of the polymer.^[95]

Table 1 Glass transition temperature (T_g) of Eudragit® RS 30 D polymeric films as a function of plasticizer type and concentration

Plasticizer	T_g of Eudragit® RS 30 D ^a	
	10% Plasticizer	20% Plasticizer

Acetyl tributyl citrate	38.2	22.2
Triacetin	42.2	27.4

^aUnplasticized film is 55.0 °C.

(From Ref. 93.)

Mechanical Properties

Basic research with polymeric solutions and dispersions has focused on the mechanical properties, including tensile strength, Young's modulus, and elongation. Mechanical testing has been used to evaluate the effectiveness of plasticizers,^[33,90] as well as the permeability of film coatings^[96] and the dissolution characteristics of film-coated solids.^[97,98] Mechanical data obtained from tensile testing of free films have been used to predict the incidence of film defects in coated tablets.^[99] These mechanical data have also been used to make predictions regarding the long-term storage stability of film-coated solid dosage forms.^[100]

Common methods used to evaluate mechanical properties of polymeric films include microindenter probe analysis,^[101] puncture and shear tests,^[35,102] and stress relaxation.^[103] The stress–strain test is probably one of the most popular and widely used techniques to determine the mechanical properties of polymeric materials of pharmaceutical interest.^[104,105] Stress–strain testing generally consists of applying an axial load to an isolated free film and measuring the load and deformation simultaneously. The stress–strain test will provide a generalized curve from which several useful properties can be determined. A typical stress–strain curve obtained from tensile testing is shown in Fig. 9 and illustrates the terminology used. During the tensile test, initially there is a linear portion of the curve where the elongation of the polymeric film is directly proportional to the applied stress, and the slope of this linear region is known as Young's modulus. Young's modulus is a measure of the stiffness of the film or the ability of the film to withstand high stress while undergoing little elastic deformation. The greater the slope of the line, the higher the modulus and the greater the stiffness of the polymeric material. The plateau area where

Film Coating of Oral Solid Dosage Forms

Fig. 9 Example of a stress–strain curve obtained in the tensile testing of isolated free films.

the film first undergoes a marked increase in strain without a corresponding increase in stress is known as plastic deformation. During plastic deformation, the structure of the polymeric film changes as the polymer chains orient themselves parallel to the direction of flow. As the film continues to be elongated, a point is reached at which the film breaks, known as the elongation at break. The stress value at this point is referred to as the ultimate tensile strength, which is a measure of the ability of the solid to withstand fracture. The area under the curve represents the work done and is referred to as the toughness of the polymer.

Using tensile testing of free films, researchers have shown that plasticizer type and concentration influence the mechanical properties of both acrylic and cellulosic polymers.^[33,106] Fig. 10 shows the influence of dibutyl

Fig. 10 Influence of dibutyl sebacate concentration on the stress–strain curve of isolated free films prepared from an ethyl cellulose aqueous dispersion (Aquacoat®). (From Ref. 107.)

sebacate concentration on the tensile properties of free ethyl cellulose films.^[107] As the concentration of the plasticizer was increased from 25% to 35%, the elongation at break increased and the slope of the curve decreased, indicating the film became more flexible. Storage conditions and aging have also been found to affect the mechanical properties of polymeric films.^[108,109]

The mechanical properties determined by tensile testing of isolated free films in the dry state may not predict the behavior of the coated dosage form when in contact with biological fluids.^[102] During the dissolution process, aqueous fluids will diffuse through the film coating into the solid core and the polymeric film will be in a hydrated or wet state. Table 2 shows the mechanical

Table 2 Mechanical properties of dry and hydrated films prepared from different polymeric dispersions plasticized with 20% (w/w) triethyl citrate (standard deviation in parentheses)

^aFilms did not rupture.

(From Ref. 35.)

properties of dry and wet acrylic and cellulosic films determined using a puncture test technique and these data clearly demonstrate that the strength and flexibility of hydrated films may be quite different from films in the dry state. For example, while brittle when dry, Eudragit L 30 D was significantly more flexible when hydrated, presumably due to the plasticizing effect of water.^[35] Bodmeier and Paeratakul^[102] also found that the solubility of the plasticizer incorporated in the film coating formulation influenced the mechanical properties of hydrated films. Triethyl citrate, a water-soluble plasticizer, leached from an acrylic film upon exposure to water, thus causing significant differences in the mechanical strength of dry and hydrated films. In contrast, no significant differences in the mechanical properties of wet and dry films containing the water-insoluble and nonleaching plasticizer acetyl tributyl citrate were noted.

While tensile testing of free films has been the traditional method used for studying the mechanical properties of polymers, compression tests have been to a lesser extent.^[110] Many similarities exist between tension and compression tests, including the manner of conducting the test and the analysis and interpretation of the results. Uniform displacement rates are applied in a manner similar to a tensile test, except for the direction of loading. One of the advantages of compression testing is that the effects of substrate materials, storage conditions, and physical aging on the mechanical properties of applied polymeric films may be investigated. Compression testing of coated solids has also been used to determine qualitatively the adhesive properties of polymers, with single peak failure indicative of high substrate/coating adhesion.^[3] Fig. 11 shows the force–deflection profiles obtained from compression testing of enteric-coated soft gelatin capsules. In most cases, the capsule shell and the polymeric film fractured simultaneously, as shown in Fig. 11A, indicating good adhesion. Fig. 11B shows that some of the coated soft gelatin capsules exhibited a break in the film followed by rupture of the gelatin shell, which the authors attributed to poor film–capsule adhesion.^[9]

Compression testing of coated pellets has recently received attention in the pharmaceutical literature, as researchers compress these pellets into the more tamper-resistant tablet dosage form.^[111,112] Methods to quantify the compression properties of coated pellets have been discussed elsewhere.^[113,114] The compressional forces used during tableting are critical and, if these forces exceed the strength of the coating, the film will fracture and faster dissolution rates will result.^[115] Due to the intensive contact during compression, slower drug release may also occur as the films from the coated pellets fuse together to form a matrix tablet.^[40] Readily compressible

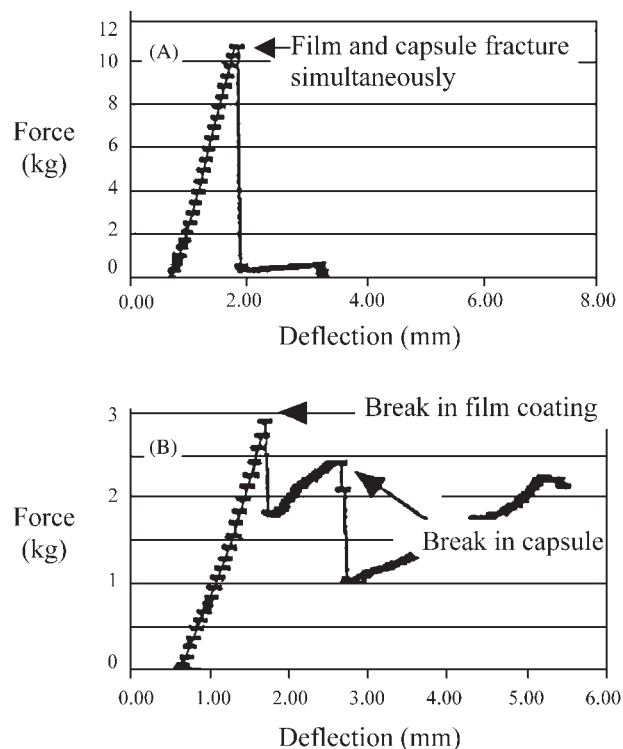

Fig. 11 Force–deflection profiles of soft gelatin capsules containing polyethylene glycol as a fill liquid and coated with Eudragit® L 30 D-55 obtained from compression testing: (A) polymer plasticized with 20% triethyl citrate; (B) polymer plasticized with 20% tributyl citrate. (From Ref. 9.)

excipients, such as starch and microcrystalline cellulose, have been dry blended with coated pellets prior to tableting to eliminate the possible fracture or fusing of the polymeric films. These excipients prevent direct contact of the coating and reduce friction during compression. The addition of at least 15% (w/w) microcrystalline cellulose to coated acetyl salicylic acid pellets was shown to prevent the formation of matrix tablets.^[116]

Polymer Adhesion

Good adhesion between a polymer and the surface of a solid is a major prerequisite for the film coating of pharmaceutical dosage forms.^[117] Poor adhesion may result in flaking or peeling of the coating from the solid substrate during storage, which could significantly jeopardize film functionality. Loss of adhesion may lead to an accumulation of moisture at the film–tablet interface, affecting the stability of drugs susceptible to hydrolytic degradation.^[118] Loss of adhesion may also compromise the mechanical protection the coating

provides to the solid substrate.^[3] In addition, experiments on adhesion may be useful to the pharmaceutical scientist during preformulation studies to investigate the relationship between tablet excipients and polymeric coating formulations.^[119]

Force involved in adhesion

The two major forces that have been found to affect polymer–tablet adhesion include the strength of the interfacial bond and the internal stresses within the coating. For pharmaceutical products, hydrogen bond formation is the primary type of interfacial contact between the tablet surface and the polymer. Dipole–dipole and dipole-induced dipole interactions also occur to a lesser extent. Factors that affect the type or the number of bonds formed between the polymer and the solid surface will influence film adhesion.^[117]

The second major factor influencing polymer adhesion is the internal stresses within a film. When a polymeric solution or dispersion is applied to a substrate, internal stresses inevitably develop within the coating.^[120] These stresses include stress due to shrinkage of the film upon solvent evaporation, thermal stress due to the difference in thermal expansion of the film and the substrate, and volumetric stress due to the volume change when a substrate swells upon storage. Several researchers have developed equations to estimate the total stress within a film.^[120,121] The total internal stress, P , may be calculated using Eq. 2:

$$P = \frac{E}{3(1-\nu)} \left[\frac{\phi_s - \phi_r}{1 - \phi_r} + \Delta\alpha_{\text{cubic}} \Delta T + \frac{\Delta V}{V} \right] \quad (2)$$

where E is the elastic modulus of the film, ν is the polymer's Poisson's ratio, ϕ_s is the volume fraction of the solvent at the solidification point of the film, ϕ_r is the volume fraction of the solvent remaining in the dry film at ambient conditions, $\Delta\alpha_{\text{cubic}}$ is the difference between the cubical coefficient of thermal expansion of the film coating and the substrate, ΔT is the difference between the glass transition temperature of the polymer and the temperature of the film during manufacturing and storage, ΔV is the volumetric change of the tablet core, and V is the original volume of the tablet core. While this equation has been derived for polymeric solutions, the theory is applicable to polymeric dispersions as well. From Eq. 2, the total stress within a film is directly proportional to the elasticity of the polymer. Therefore, factors that influence the elastic modulus of the polymer may affect film–tablet adhesion.

Methods to assess adhesion

The small size of the tablet and the nonuniform surface roughness of the substrate have presented significant challenges to the pharmaceutical scientist in assessing the adhesive properties of polymers. In the 1970s, film–tablet adhesion was assessed using a peel test, where a modified tensile tester peeled the film from the surface of the tablet at a 90° angle.^[122] The peel angle, however, is dependent on both the elasticity of the film and the uniformity of adhesion, which may produce significant deviations in the data.^[123] More recently, several variations of the butt adhesion technique have been reported in the pharmaceutical literature.^[122,127,128] Although similar to the peel test, the entire film is removed normal to the surface of the tablet, rather than sections of the film being peeled. The butt adhesion technique eliminates variations due to the elasticity of the film and is less influenced by the uniformity of adhesion. Using the butt adhesion test, force–deflection profiles can be generated, an example of this is shown in Fig. 12. This graph, similar to stress–strain curves commonly generated in the tensile testing of free films, permits the visualization of the development of the force within the sample during the adhesion test. In addition to the force of adhesion, the elongation at adhesive failure, the modulus of adhesion, and the adhesive toughness of the film can be determined. The elongation at adhesive failure is the distance the upper plate traveled at film separation. Analogous to the elongation at break obtained from tensile testing of free films, elongation at adhesive failure reflects the ductility of the polymeric film.

Fig. 12 Example of a force–deflection profile obtained from a butt adhesion experiment.

The modulus of adhesion is the slope calculated from the linear region of the force–deflection diagram and may be compared to Young's modulus obtained from tensile testing of free films. The adhesive toughness is the work required to remove the film from the tablet surface and may be calculated from the area under the force–deflection profile.

Substrate variables affecting adhesion

The surface roughness of the tablet compact and the force of compression used during tableting will affect polymer adhesion, by altering the effective area of contact between the film coating and the surface of the solid. The compressional force used during tableting has been found to significantly influence adhesion of organic-based cellulosic films, as shown in Fig. 13.^[123] Above a critical force, increased compression during the tableting process resulted in decreased adhesion. Below the critical compression pressure, the tablet laminated, rather than the film being separated from the tablet surface, and cohesive failure occurred. In the same study, a relationship between tablet porosity and polymer adhesion was found, as shown in Fig. 13, which the authors attributed to the extent of solvent penetration into the substrate cores and the physical mixing at the film–tablet interface. Using aqueous-based acrylic dispersions, Felton and McGinity^[119] also reported stronger adhesion when the polymer was applied to rougher tablet surfaces.

Because adhesion is primarily due to hydrogen bond formation, hydrophobic excipients in the tablet may decrease adhesion by presenting a surface consisting of mainly nonpolar hydrocarbon groups. As shown in Fig. 14, increased concentrations of stearic acid, a commonly used

Fig. 13 Influence of compression pressure on the (▲) porosity and adhesion of film formulations containing (●) low viscosity and (■) high viscosity hydroxypropyl methylcellulose: (A) porosity (%); (B) adhesion (kPa). (From Ref. 123.)

Fig. 14 The effect of lubricant concentration (% w/w) on the measured adhesion (kPa) of hydroxypropyl methylcellulose films: (A) Pharmacoat® 606; (B) Methocel® 60HG viscosity 50; (▲) stearic acid; (●) magnesium stearate; (■) calcium stearate. (From Ref. 124.)

lubricating agent that has a free polar carboxyl group, improved adhesion of an organic-based cellulosic polymeric film.^[124] When more hydrophobic lubricating agents were added to the tablet compacts, polymer adhesion decreased. Increased concentrations of magnesium stearate in tablets have also been shown to significantly lower adhesion of aqueous-based acrylic and cellulosic films.^[119,125] In contrast, the addition of microcrystalline cellulose to tablets improved film–tablet adhesion, presumably due to the saturation of the tablet surface by hydroxyl groups of the excipient.^[124,125]

Film coating variables affecting adhesion

Several studies have shown that the solvent system used in the coating formulation affects polymer adhesion.^[126] The solvent will interact with the polymer and will affect the random coil structure of the polymer chains. It is generally accepted that the greater the polymer–solvent interaction, the greater the end-to-end distance, thus exposing more of the polymer that is capable of interacting with and binding to the surface of the solid. Nadkarni et al.^[127] suggested that the solubility parameter of the solvent be used as a qualitative measure to the extent of polymer solvation, with greater polymer solvation resulting in greater film–tablet adhesion. In 1988, Rowe^[128] developed equations using the solubility parameters of the tablet excipients and the polymer to predict trends in film–tablet adhesion. Wood and Harder^[122] used contact angle measurements, as an indication of surface wettability, to predict polymer adhesion. In contrast, Felton et al.^[74] added surfactants to acrylic dispersions to alter substrate wettability. These researchers suggested that tablet wettability is not a valid

Table 3 Influence of the plasticizer in the coating formulation on the force of adhesion and the glass transition temperature (T_g) of an acrylic resin copolymer (standard deviation in parentheses)

Plasticizer	Force of adhesion (kg)	T_g (°C)
Triethyl citrate	4.85 (0.27)	36.5 (1.1)
Polyethylene glycol 6000	4.32 (0.25)	38.6 (2.5)
Tributyl citrate	3.81 (0.30)	51.2 (2.2)
Dibutyl sebacate	3.48 (0.33)	62.0 (3.6)

(From Ref. 129.)

predictor of adhesion of polymeric dispersions, because it is the polymer that binds to the substrate, not the solvent.

One of the two major forces influencing polymer adhesion is the internal stress within the polymeric film.^[120] The addition of plasticizing agents to coating formulations generally decreases the internal stress in the film by decreasing both the elastic modulus (E) and the glass transition temperature (T_g) of the film coating (Eq. 2). Felton and McGinity^[129] demonstrated a relationship between adhesion and the T_g of the polymer. As shown in Table 3, film–tablet adhesion was strongest in the more plasticized films. The researchers attributed these findings to the extent of the polymer–plasticizer interactions and the effectiveness of the plasticizing agent in lowering the internal stresses within the film coating. Higher concentrations of plasticizers within polymeric films caused a slight decrease in the force of adhesion and a significant increase in the elongation at adhesive failure and adhesive toughness, as shown in Fig. 15.^[129] These findings were

**Fig. 15** Influence of triethyl citrate plasticizer concentration on the force–deflection profile of Eudragit® L 30 D-55 applied to tablet compacts: (■) 20% plasticizer; (●) 30% plasticizer. (From Ref. 129.)

again attributed to a lowering of the internal stresses within the film and an increase in the elasticity of the polymer. Interestingly, adhesion was also found to be dependent on the physicochemical properties of the plasticizer in conjunction with the surface hydrophobicity of the tablet compacts, with films containing hydrophobic plasticizers being less sensitive to the hydrophobicity of the substrate.^[129]

Insoluble additives in coating formulations, including talc, titanium dioxide, and other pigments have been found to influence polymer adhesion.^[118] These insoluble excipients generally cause an increase in the internal stresses within the film and are thought to embed themselves at the film–tablet interface.^[70,117] The extent to which excipients incorporated into film coating formulations may affect polymer adhesion is dependent on the particle size, concentration, and morphology of the insoluble agents in the coating.^[56,69,118,125]

Processing parameters affecting adhesion

Dimensional changes in the tablet core that occur during the coating process will influence the internal stresses within the films of the final coated products and may ultimately affect polymer adhesion.^[130] The extent of substrate swelling is dependent on the temperature used during processing. Rowe^[131] suggested that the excipients in the tablet core and the polymeric coating materials should have similar coefficients of thermal expansion to minimize the development of internal stresses in the film during processing.

The postcoating drying or curing stage of processing may affect polymer adhesion. As the solvent evaporates and the polymer droplets coalesce, the number of potential polymer–substrate binding sites increases, as shown in Fig. 16. Felton and Baca^[14] showed that film–tablet adhesion increased during curing, and the force of adhesion was dependent on the hydrophobicity of both the substrate and the plasticizing agent in the film formulation. Environmental storage conditions have also been shown to influence adhesion.^[9,73,118,126,129]

PROBLEMS ENCOUNTERED DURING FILM COATING

Defects in the Film

Coated solids are generally evaluated visually to detect defects in the film^[132] and a list of common defects is presented in Table 4.^[133] Some defects may be esthetic in nature while others are more serious and may compromise the functionality of the film coating. Manipulating

Fig. 16 Schematic of the increase in potential polymer-substrate interactions as film formation proceeds: (A) closely packed polymer spheres; (B) initiation of coalescence and polymer chain interdiffusion; (C) complete film formation. (From Ref. 14.)

processing conditions, adjusting the coating formulation, or reformulating the substrate may resolve these problems. Picking, for example, occurs when tablets briefly stick together during the coating process. This defect generally occurs in an over-wet tablet bed and may be eliminated by reducing the spray rate or increasing the bed temperature.^[63] Picking may also be reduced by adding antiadherents to the coating formulation. Mottling is a blotched or spotted film coating and is associated with inadequate pigment dispersion or color migration. If the colorant is uniformly dispersed in the coating formulation, color variations within the film may be curtailed by increasing the rotational pan speed, using baffles in the coating pan, or increasing the number of spray guns used.^[134,135] A rough surface, similar to the surface of an orange, is known as the orange peel effect and occurs when the spray droplets become too viscous to spread across the substrate. Perhaps, more serious and likely to compromise film functionality, cracking and peeling of the coating occur when the internal stresses exceed the tensile strength of the film and reformulation of the coating is often required.^[132]

Characteristics of the Substrate

The physical and chemical characteristics of the substrate are important considerations in film coating. Substrates, for example, must be sufficiently robust to physically withstand tumbling in the coating apparatus. Weak tablets may chip or fracture during coating and slower rotational

Table 4 List of common defects that may occur during film coating

Defect	Description
Blistering	Film becomes locally detached, forming a blister
Blooming	Dulling of coating
Blushing	White specks or haziness in film
Bridging (of the intagliation)	Film pulls out of intagliation or monogram forming a bridge across the mark
Chipping	Film becomes chipped
Color variation	Intertablet variation in color
Cracking	Film cracks across the crown of the tablet
Cratering	Volcanic-like craters in film
Flaking	Film flakes off exposing tablet surface
Infilling	Intagliation filled by solidified foam
Mottling	Uneven distribution of color (intratablet)
Orange Peel	Film rough and nonglossy surface like skin of orange
Peeling	Film peels back from edge exposing tablet surface
Picking	Isolated areas of film pulled away from surface
Pitting	Pits in surface of tablet core without disruption of film
Roughness	Film rough and nonglossy
Wrinkling	Film with wrinkled appearance

(From Ref. 133.)

pan speeds may be required. Interactions between the substrate core and the film coating may occur as the polymeric solution or dispersion physically mixes at the interface.^[95,98,136–138] Pitting has been reported to occur when coating tablets containing low melting excipients, such as stearic acid.^[139] Drugs may also interact with excipients in the film coating formulation.^[140] A seal coat or subcoat may be necessary to separate the reactive components and eliminate these types of interactions.

Sustained release wax matrix tablets are generally considered difficult to coat with aqueous polymeric dispersions due to the poor wettability of the hydrophobic tablet surface.^[141] The physicochemical characteristics of the substrate have also been shown to affect the mechanical and adhesive properties of the polymer.^[69,119] Adhesion problems have been reported when coating both hard and soft gelatin capsules.^[8,9,142] The capsule shell is relatively smooth and generally provides less surface area for interfacial contact compared to tablet compacts.^[143,144] The hydrophobicity of the fill liquid of soft gelatin capsules in conjunction with the plasticizer used in the coating formulation has been shown to influence polymer adhesion.^[9] Adhesion may be improved by adding polyethylene glycol 400 or 6000 to the coating formulation or using subcoats of hydroxypropyl cellulose or hydroxypropyl methylcellulose.^[117]

In addition to adhesion problems, other difficulties attributed to the physical properties of gelatin have been reported in coating capsules with aqueous polymeric formulations. The capsule halves may separate during the coating process due to the tumbling movements of the coating pan. During coating, the capsule shell may become either sticky due to solubilization of the gelatin or brittle due to water evaporation. Thus, the bed temperature and the polymer spray rate become even more critical parameters in capsule coating processes. In addition, a prewarming stage is required when coating soft gelatin capsules.^[8,9] The temperature of the fill liquid must be raised to that of the bed temperature to allow for uniform drying of the film.

Physical Aging

Another critical problem that may occur with film-coated products is a change in drug release rates over time and is generally associated with aging. The majority of polymers used in pharmaceutical products are amorphous and are not at thermodynamic equilibrium at temperatures below their glass transition temperatures. During time, amorphous polymers undergo a slow transformation toward a thermodynamic equilibrium. A schematic representation of this process is shown in Fig. 17. As temperatures are

Fig. 17 Schematic of the origin of physical aging in amorphous polymers.

cooled to below the glass transition temperature of the polymer, the free volume of the polymer will slowly relax toward a lower free energy state over time. This process is referred to as physical aging. Ali and Sheldon^[145] demonstrated that a structural reorganization of the polymer chains occurs during aging. Researchers have shown that aging significantly impacts the long-term stability of film-coated products, affecting the permeability, mechanical, adhesive, and drug release properties.^[100,108,146,147] Complete coalescence of the film coating is critical to minimize physical aging effects.^[148] Finally, it should be noted that polymers used in the coating of pharmaceutical dosage forms are sensitive to environmental storage conditions, and temperature and humidity can significantly alter polymer properties.^[15,18,83,100,108,109]

CONCLUSIONS

Cellulosic and acrylic polymeric films have been used to coat pharmaceutical drug products for decorative, protective, and functional purposes. These materials are generally applied using a spray-atomization technique. Additional excipients, including plasticizers, pigments, antiadherents, and surfactants, may be incorporated into the coating formulation to aid in processing or to improve the esthetic appearance of the coated solid. The addition of these excipients, however, may alter polymer properties and affect drug release rates. In the development of a film coating formulation, various polymer properties are commonly evaluated and these data are used to make predictions regarding the dissolution characteristics and

long-term stability of the final product. Adhesion of the polymer is critical to the performance of the film and may be affected by the physicochemical properties of the substrate, additives in the coating formulation, and processing conditions. Subcoats have been used to improve polymer adhesion as well as to separate reactive components in the film and substrate. Defects in the polymeric film may be eliminated by adjusting processing parameters or by reformulating the coating and/or the substrate. Aging of coated solids may cause changes in the drug release characteristics and polymeric films should be completely coalesced to minimize aging problems.

Freeze Drying, Scale-Up Considerations

Edward H. Trappier

Lyophilization Technology, Inc., Ivyland, Pennsylvania, U.S.A.

INTRODUCTION

Product presentation, formulation, and processing are integral in their influences on the outcome of manufacturing a lyophilized product. Activities in development involve knowledge of the clinical and stability requirements, formulation and product design, and investigation into suitable processing conditions. These activities incorporate the awareness that the product is expected to be integrated into large-scale routine manufacturing of commercial product. Multiple steps and increasing batch sizes are often necessary as the product progresses through clinical studies and market introductory batches. Aspects of equipment, processing capabilities, processing influences, and finished product attributes all need to be considered in the scale-up to increasingly larger batch sizes on the pathway of taking a product to market.

DEVELOPMENT AND SCALE-UP PATHWAY

In the progression of bringing a new product to the market, scale-up from the initial development batches to commercial manufacturing is an important activity. This progression includes transferring the technology for producing a product after sufficient initial development, eventually integrating the procedures into a commercial manufacturing environment. As part of later development activities, materials for stability and early clinical studies are commonly prepared on a small scale. This comprises the first transfer of the processing methods into a manufacturing environment. Following successful clinical results, the product presentation and any refinements to the manufacturing procedures are implemented, and the process is duplicated on a larger scale in a manufacturing environment for full commercial production.

With an approved investigational new drug (IND), a new drug entity is developed into a new product with administration to human patients for establishing safety, efficacy, and dosing regime in phase I through phase III clinical studies. Initial development activities focus on preparing materials for conducting these studies. Meeting the needs of supplying the clinical material often results in initial product presentations that may be different than the final product that is introduced to the market. As clinical

trials progress, active pharmaceutical ingredient (API) manufacturing, analytical methods, product design, and manufacturing procedures are developed and refined. With the success of early clinical trials and entering into phase III clinical studies, product preparation and specifications are finalized. The API is well characterized, analytical methods are validated, product presentation and specifications finalized, as well as finished product processing procedures established.

Initial development activities are focused on preparing to supply early clinical requirements and product needs in designing the product formulation and presentation. The product presentation is based upon optimal administration to the patient in a clinical setting and stability requirements for the active ingredient. Lyophilization is used as a method of preservation for products that are sensitive to the presence of water and have limited stability as a liquid ready-to-use preparation. This low temperature vacuum drying process removes the water, leaving a dried solid, resulting in sufficient stability to allow long-term storage. At the time of use, the product is reconstituted with a diluent that returns all the attributes of a liquid ready-to-use product, yielding the preparation suitable for administration. One advantage to a lyophilized preparation is the different concentrations of API that may be obtained by varying the diluent volume for reconstitution, along with the volume used for administration, to allow for different dosages from a single preparation. Once the initial product presentation suitable for the early clinical studies is identified, processing procedures can then be developed. The focus for the initial lyophilization process is robustness and ease of scale-up rather than optimal parameters for routine manufacturing. In practice, the presentation initially developed may not necessarily be the final product marketed; the product presentation may change as a result of clinical studies. Continued development activities often then encompass a series of refinements to the product and procedures. In the pathway of bringing a new product to the market, scale-up and technology transfer may therefore occur multiple times.

As the product progresses through stages of development and clinical studies, product and process design are refined. Processing experience is gained on increasingly larger scale batches as the demands for clinical material increases. Finally, phase III clinical studies require

product quantities that may approach batch sizes closer to those that are typical of full-scale commercial manufacturing. Fig. 1 describes objectives and environment in the progression of steps in taking a product from initial development to manufacturing-scale operations. Initial success along with expanded indications throughout the life cycle of a product may continue to require larger batch sizes to meet increasing market demand. With the evolution of the product from development to clinical studies, followed by initial introduction and potential growth with market expansion, scale-up begins with smaller and progresses to increasingly larger batch sizes.

Design of a preparation and development of a suitable lyophilization process is first conducted in the laboratory. Product design focuses on the formulation and presentation. Stabilizing the API, imparting necessary features for patient administration, and constructing desirable dried product attributes are the objective in developing an appropriate formulation. Coupled to those objectives are the concentration, dictating product presentation parameters of fill volume, as well as selection of the container and closure. The formulation and presentation both influence the conditions required for the lyophilization process.

In development, variations in critical process parameters are explored. Preparation for integrating a new product and the associated new procedures into manufacturing warrants a thorough understanding of the product and methods necessary to produce material. These manufacturing methods need to be effective and adequately controllable for both a small scale for early clinical studies, later to be refined for batches to be processed in routine manufacturing of commercial product. Manufacturing capabilities may be an existing in-house operation or at another facility providing contracted manufac-

turing services. Where the finished product is produced often influences the accessibility of information in learning the capabilities of manufacturing and the ease of technology transfer during the scale-up.

The focus in initial development of a potential new product is designing a product and suitable processing methods for the early clinical studies. With clinical success yet established, lyophilization process development is focused on short-term objectives and the efforts limited: time is of the essence. Results of early clinical studies direct refining the product design and processing procedures as clinical trials progress. Priority is given to designing a product presentation that is suitable for the intended route of administration, convenient to use with sufficient flexibility in dose administration in the clinic, and provides sufficient stability for the duration of the clinical studies. Often with limited knowledge, experience, and amounts of API at the time of early clinical studies, there is little opportunity for extensive product design and process development. The objective is to focus on an adequate product design for completing the studies and sufficiently conservative process for ease of technology transfer and scale-up.

At these early development stages, an “optimized” process is one that is safe, robust, efficient, and effective with minimal risk of difficulties in producing clinical materials, and not necessarily what would be considered the shortest. Challenges of transferring the product from early development to producing early clinical supplies involve availability of raw material, appropriate product design, and manufacturing capability. Often at the time clinical studies are beginning, processing methods for raw material are still evolving, the API material is not yet well characterized, and is in limited supply. With pressures to

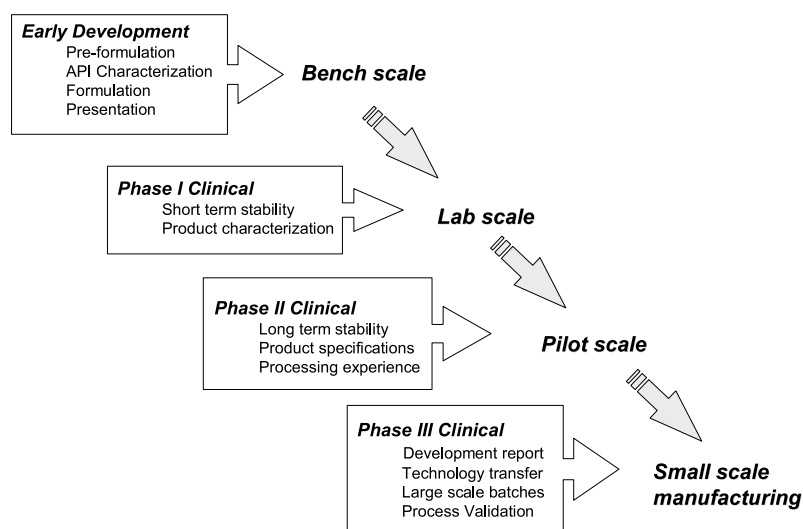

Fig. 1 Objectives and operations in progression to manufacturing scale. (View this art in color at www.dekker.com.)

begin clinical studies, the timeline of a project is often accelerated and the transfer to a manufacturing facility is considered the last link in a series of efforts. With decisions made on the basis of only a few development studies and limited data, the objective of the scale-up of early clinical manufacturing is to manage the level of risk with a process that is suitable but not necessarily conducive for large-scale commercial manufacturing.

As clinical studies progress, development efforts can begin to focus on the final product design and process parameters established through expanded studies in the laboratory. Objectives for these studies become improvements in the procedures that are well suited for routine processing in a manufacturing environment. These activities would also include process validation studies. The scope and extent of the validation studies expand as batch sizes increase with the progression from development to commercial manufacturing. Fig. 2 provides a graphic representation of the development efforts and activities along with the extent of validation appropriate as API production, finished product manufacturing, and analytical methods are refined in preparation for increasing batch sizes progressing toward large-scale commercial manufacturing.

The success of development efforts is measured by the ease of technology transfer and scale-up to large-scale manufacturing. Small-scale studies in the laboratory need to incorporate influencing factors of large-scale manufacturing. The intent is to develop a process that is safe,

effective, efficient, and sufficiently robust where the manufacturing technology can be transferred to routine large-scale commercial production. Product-design objects are efficacy, stability, safety, and ease of use. Process design entails establishing desirable finished product attributes and ease of reproducible manufacturing that consistently results in high quality and yield, at a low unit cost. The formulation, product design, and process all have an influence on each other, with consideration of the impact of one on another being of significant importance during development.

PRODUCT DESIGN

Characteristics of the product and functions in early clinical studies are the driving force for initial product development. Often, there is a nominal knowledge of the API characteristics at such an early juncture. Preformulation studies provide attributes such as solubility, effects of pH, and predict sensitivities to environmental conditions. Solubility, along with pharmacologic characteristics, dictates the volume in the product container. Sensitivities to environmental conditions include temperature, light, oxygen, and contact surfaces. Specific to lyophilized preparations, there is also the potential for degradation via hydrolysis reactions when in the presence of water. Each of these aspects, in particular the sensitivities to environmental

Progression of product to market introduction; development efforts and extent of validation with relative batch sizes.

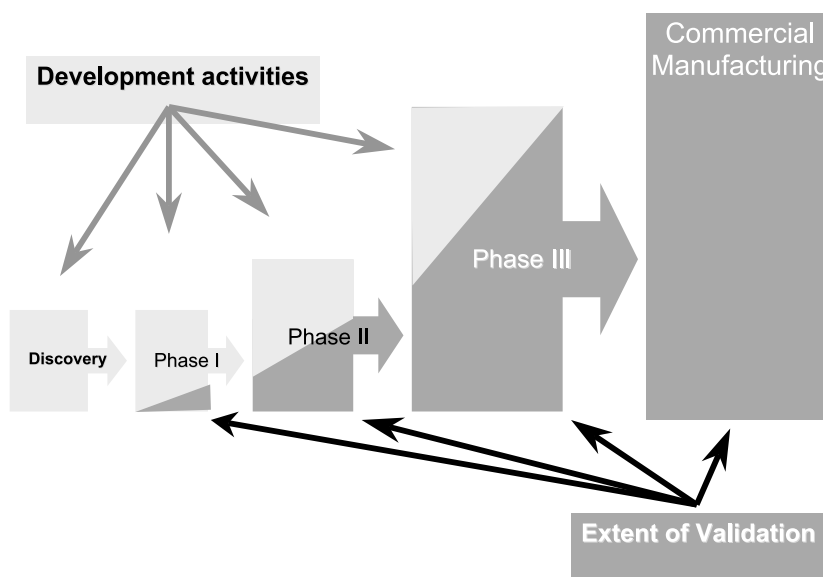

Fig. 2 Batch size, development efforts, and extent of validation. (View this art in color at www.dekker.com.)

conditions, needs to be considered during preformulation and development studies in preparation for scale-up.

Aspects of selecting a product container include both initial fill volume for dispensing in manufacturing and volume used for reconstitution, along with ease of use in a clinical setting. Later considerations include batch size capacity in a lyophilizer during commercial manufacturing. Smaller-diameter containers yield increased number of units per shelf surface area in a lyophilizer, and therefore larger batch size. This has an impact on manufacturing unit costs as well as the ability to later meet growing market demands. There may be occasion that the container size changes as the product moves from early clinical studies to product approval for commercial manufacturing. Such changes should be expected and are often unavoidable. Source of the container may also change as the product is scaled up. It is therefore prudent to evaluate different sources of containers during development, qualifying at least a primary and a secondary supplier in preparation for routine manufacturing. This would also apply to elastomeric closures used to complete the primary barrier of the container-closure system for the finished product. Product compatibility, manufacturability, and container-closure integrity all need to be evaluated for both primary and alternate components, avoiding single-source materials.

FORMULATION DESIGN AND PRODUCT CHARACTERIZATION

The nature of the product, requirements for stabilization, route of administration, and processing are all factors that influence the design of the product formulation. Specific details of these aspects are beyond the scope of this presentation and have been addressed by Pikal elsewhere in this encyclopedia. As product development and scale-up occur through the progression of preparing material for clinical studies and subsequent commercial manufacturing, it is expected that a growing body of data is generated. Such data are important in characterizing the product and understanding the critical needs, sensitivities, and behavior of the product. Analysis of a lyophilized product provides insights that are helpful in scaling up to larger batch sizes with the potential of being processed in varying environments. Along with evaluating attributes of a lyophilized preparation, finished product specifications are developed.

As upstream manufacturing progresses from small- to larger-scale processing, quality attributes of the API material may change. These changes may influence the behavior in the finished product. Analysis of the API for monitoring any changes encompasses potency and purity.

Low-temperature thermal analysis is also warranted for assessing any impact of changes in the API. Changes in quality and purity can have an influence on the phase transition of the solution, influencing the behavior during freezing and the threshold temperature during drying. Quality and purity attributes of the raw material need to be evaluated for the impact on downstream processing and finished product attributes as the upstream processing for the API is scaled-up or significant changes are made.

The formulation and product presentation may require adjustments as the product progresses through clinical studies. Concentration of the active and dose content may be adjusted for materials in later clinical studies. If the changes are nominal, then there may be little need for adjustment to the process. Significant changes warrant further development as the lyophilization processing conditions require refinement and may require subsequent scale-up studies.

PRODUCT PREPARATION

Conditions having no apparent impact during development activities can become more significant during larger-scale manufacturing. These include length of time the product exists as an aqueous solution and exposure to widely different environmental conditions. As batch sizes increase through clinical materials preparation to large-scale manufacturing, the time interval from when the API is first compounded to form a solution to when the product is frozen and lyophilized becomes extended. A small batch may be formulated on the bench requiring only a few hours to compound, filter, fill, and begin lyophilization. In routine manufacturing, the bulk solution may be formulated and held for hours prior to sterile filtration and filling. The difference in time required for preparation of a batch may warrant reducing the temperature of the solution to minimize degradation reactions. If Arrhenius behavior applies for temperature dependence of rate constants for reactions, degradation would be significantly reduced by maintaining the bulk solution at 5°C during storage rather than 25°C. Such practices are appropriate when the stability of the product as a bulk solution is limited.

The vessel used for the compounding may be different during development simply because of batch size. Compatibility with these different materials is important to consider in preparation for scale-up. Bench-scale studies and small clinical batches may be compounded in glass Erlenmeyer flasks or glass carboys. Commercial-scale manufacturing would typically use larger stainless steel tanks. Compatibility with the different materials that the product comes into contact with is important to evaluate.

Volume-to-surface-area ratios may change based on the configuration of the bulk solution container. This affects exposure to the air and absorption of oxygen and carbon dioxide. To limit the effect of such sensitivities as with oxygen, an antioxidant may be included in the formulation. Extent of exposure to light may also be different when preparing larger-quantity bulk solutions. Such sensitivities are important to explore in preformulation and early development studies and considered during scale-up.

LYOPHILIZATION PROCESS DEVELOPMENT

Part of the development studies focused on defining the critical process parameters to be controlled and that achieve reproducibility of the process and consistency of the finished product. An integral part of the development activities for a lyophilized product is establishing appropriate process parameters that encompass loading the liquid-filled containers through stoppering and unloading dried product from the lyophilizer. The lyophilization process encompasses loading, freezing, and any type of thermal treatment, primary and secondary drying, stop-

Table 1 Lyophilization process description: model presentation

Step	Processing parameters
Loading	Soak at 5°C ($\pm 5^\circ$) and 1 atm for 2 hr
Freezing	Ramp shelf to -40°C at an average controlled rate of 30°C/hr Control shelf at target set point of -40°C ($\pm 5^\circ$) for 3 hr
Primary drying	Evacuate chamber, control at a target set point of 80 μHg (± 20 μHg). Ramp shelf to -10°C at an average controlled rate of 30°C/hr Control shelf at target set point of -10°C ($\pm 5^\circ$) for 15 hr
Secondary drying	Control chamber pressure at a target set point of 80 μHg (± 20 μHg). Ramp shelf to 30°C at an average controlled rate of 30°C/hr Control shelf at target set point of 30°C ($\pm 5^\circ$) for 5 hr
Stoppering	Control chamber pressure at a target set point of 1 atm Control shelf at target set point of 30°C ($\pm 5^\circ\text{C}$).

Table 2 Lyophilization process control recipe: lysozyme model presentation

	Process conditions		Segment
	Shelf temperature	Pressure	Time
Loading	Soak: 5°C	atm	2 hr
Freezing	Ramp: 30°C/hr	atm	1.5 hr
	Soak: -40°C	atm	3 hr
Primary drying	Ramp: 30°C/hr	80 μHg	1 hr
	Soak: -10°C	80 μHg	15 hr
Secondary drying	Ramp: 30°C/hr	80 μHg	0.6 hr
	Soak: 30°C	80 μHg	5 hr
Stoppering	Soak: 30°C	atm	Total: 27.2 hr

pering, and unloading. Critical processing parameters for these steps are shelf temperature, chamber pressure, and time. These parameters are considered to be independent as they are variables under direct control and affected only by the control implemented during the process. Table 1 outlines a process description that details the independent parameters used for processing a model presentation consisting of a lysozyme formulation representing a protein preparation. A corresponding recipe used in programming an automated control system is illustrated in Table 2. Fig. 3 represents a graphical recording from lyophilizing a batch when executing processing parameters outlined in Table 2. The graph illustrates the implementation of the independent parameters of shelf temperature, chamber pressure, and time, along with the resultant product temperature profile. Note that the product is maintained below a threshold temperature to assure drying with retention is accomplished. The sudden rise in product temperature, termed a "break," reflects the sublimation front passing the temperature sensor. If the sensor is located in the bottom of the container, then this break indicates that all of the ice in the container has sublimed. The product temperature then increases, approaches the shelf temperature, at which time it is appropriate to implement the parameters suitable for desorption in secondary drying. Understanding the impact of the critical process parameters on product behavior is important in developing a sufficiently robust process and controlling the variables during scale-up.

Numerous studies have demonstrated the impact of shelf temperature on product temperature and rates of sublimation. As DeLuca demonstrated in his studies presented in 1984, the effect is principally on the rate of sublimation, with some proportionate contribution to an increase in product temperature.^[1] Summarized in Table 3, the data demonstrate the effect of increasing the shelf

Processing parameters and resulting product temperature profile for a Lysozyme preparation during loading, freezing, primary and secondary drying. Note achieving a product temperature below a threshold in freezing and due to sublimation of ice in primary drying. A sudden increase or "break" in temperature during primary drying indicates the completion of sublimation.

Fig. 3 Lyophilization process: lysozyme model preparation. (View this art in color at www.dekker.com.)

temperature by 10°C, yielding a substantial increase in sublimation, sometimes nearly doubling the rate. An increase in product temperature also resulted, although the product increased no more than 2 to 3°C. As sublimation consumes heat, the heat energy removed is replaced with that provided by the shelf. The higher the shelf temperature, the greater the amount of heat provided to the product, and therefore a greater potential rate of sublimation can be achieved. With heat from the shelf driving the rate of sublimation, the evolution of water vapor from the sublimation front and the product temperature resulting from attempting to reach steady-state conditions can sometimes be a fragile balance. A limit to the amount of

heat supplied for promoting rates of sublimation is imparted by the dried layer above the sublimation front. Pikal et al. studied this relationship, modeling the effect of solutes in a formulation on the mass transfer of water vapor through the dried layer above the sublimation front.^[2] In their studies Pikal et al. characterized models of crystalline and amorphous solutes predicting resistance to mass transfer of water vapor. They also noted influences of concentration to mass transfer. There has long been and continues to be interest in modeling the effects of these independent parameters of shelf temperature, chamber pressure, and time during loading and freezing through primary and secondary drying.^[3-7] This interest is in both processing rates and impact on finished product attributes such as residual moisture.

Nail investigated the effect of chamber pressure on heat transfer and the relative rate of sublimation.^[8] Chamber pressure has a prominent effect on product temperature. Shelf temperature is the principal influence on sublimation rate; chamber pressure has a strong influence on heat transfer from the shelf to the vial and the relative difference between the vapor pressure of ice and the environment. The combined effects yield a direct impact on product temperature. The driving force of sublimation is the difference between the vapor pressure of ice in the product and the pressure of the environment. An increase in the differential increases the propensity of ice to sublime. For example, if the product temperature is

Table 3 Predicting drying rate and product temperature at various shelf temperatures

Shelf temperature setpoint	Average product temperature	Average sublimation rate
50°C	-10°C	2.43 L/hr
40°C	-12°C	2.15 L/hr
30°C	-14°C	1.51 L/hr
20°C	-17°C	1.15 L/hr
10°C	-20°C	0.68 L/hr

Source: From Ref. [1].

–32°C with a corresponding vapor pressure of ice being 321 μHg when the pressure in the product chamber is 300 μHg , the small pressure differential presents a weak driving force for the ice to vaporize. The increase in heat transfer along with the nominal rate of sublimation results in increased product temperature. With a chamber pressure of 50 μHg , a greater pressure differential would result in a stronger propensity for ice to vaporize. Greater sublimation coupled with reduced heat transfer due to lower pressure would therefore reduce the product temperature. Pikal et al. correlated the rate of sublimation to chamber pressure at a constant shelf temperature, as summarized in Table 4.^[9] The magnitude of the difference between the chamber pressure and the vapor pressure of ice at the sublimation front and the pressure differential through the layer of dried solutes above the sublimation front have a significant impact on the mass flow of water vapor evolved from sublimation at the ice–vapor interface as it travels through the dried layer. As the ice–vapor interface forming the sublimation front progresses through the initial volume dispensed into the product container, the distance the water vapor travels increases. An increased pressure differential across this distance created with a lower chamber pressure improves the flow of water vapor through the dried layer. This, in turn, decreases the water vapor concentration at the ice–vapor interface, therefore increasing the propensity of ice to sublime.

All the factors that influence desorption to achieve sufficiently low residual moisture for complete drying are not yet well understood and are an area of increasing interest to investigators. Historically, conventional wisdom purports that a lower pressure readily removes any water bound to the product after the ice has sublimed. This water may be associated with solutes where the water may be part of the amorphous composition or simply adsorbed onto the surface of the solutes. Conditions of shelf temperature and chamber pressure and their effect on achieving low residual moisture are not yet well understood and of increasing interest. Studies by Pikal et al. suggest that

reduced pressure in secondary drying does not have a significant effect on rates of desorption, at least for the model preparations and processing conditions studied.^[10]

The time associated with the different conditions is also a critical independent processing parameter. Achieving complete solidification is assured with a sufficiently low temperature for a minimum time. Factors that influence sublimation of ice during primary drying and achieving appropriate residual moisture content in secondary drying for adequate stability include sufficient time to complete the respective process step. The simplicity of time as a controlled variable is not to minimize the importance of the process parameter. Each of these three parameters, defined during development, is indeed critical and needs to be sufficient for processing, irrespective of what equipment and scale the product is processed. This includes processing at a smaller scale in early clinical materials processing or at a larger scale in routine manufacturing for marketed product.

Dependent process variables are those that result from implementing the various independent parameters under direct control during processing. As independent parameters are altered there will be some effect on the process conditions as reflected by the dependent variables. Proper control of independent variables will result in achieving the acceptable dependent variables, assuring a high level of confidence that the finished product exhibits the expected attributes. Adequately defined and executed process parameters would be expected to yield a finished product of predictable quality, purity, efficacy, and stability.

Product temperature is a principal dependent variable that reflects the progression throughout the lyophilization process. During freezing, the product is chilled to a final temperature for sufficient time to achieve the necessary solidification. The appropriate temperature required is determined by the character of the formulation and measured during thermal analysis studies completed as part of development. It is also prudent to verify the physicochemical properties if the product formulation is altered when the product progresses through clinical trials.

Even subtle differences in transferring and scaling up the process can have substantial effects in achieving this critical balance. Success during scale-up results from sufficient robustness instilled in the process during development. Initial process development activities for early clinical studies are indeed minimal. As clinical studies progress, further development work is appropriate where a process more suitable for routine manufacturing may be defined. This includes process robustness studies to establish viable ranges for critical parameters. Upon identifying target processing conditions for the independent

variables of shelf temperature, chamber pressure, and time, further studies may focus on identifying suitable boundary conditions for establishing a proven acceptable range.^[11] Variable processing conditions for such studies outlined in Table 5 and graphically represented in Fig. 4 reflect desirable ranges that yield a sufficiently robust process more easily integrated into a commercial manufacturing setting. These studies may be conducted as part of the development studies or treated separately as process validation activities. Considering these studies as either part of development or validation is not as important as the need to have completed such studies prior to scale-up to manufacturing. The greatest benefit is in

having a process that is sufficiently robust where slight variations and influences due to scale-up and transfer become inconsequential.

FINISHED PRODUCT ATTRIBUTES

The attributes of the dried product are dictated by the nature of the formulation and conditions used during processing. It is therefore desirable, if not critical, that identical processing conditions be executed on a large scale such that the quality attributes achieved during development are replicated. Any differences in the

Boundary conditions surrounding target parameters establishing a proven acceptable range listed in Table 5 for processing the model Lysozyme model preparation illustrated in Figure 3.

Fig. 4 Lyophilization proven acceptable range: lysozyme model preparation. (View this art in color at www.dekker.com.)

processing conditions can result in differences in subsequent processing steps as well as finished product characteristics. A comprehensive product evaluation scheme would include analytical assessment of the physico-chemical product aspects along with those unique to lyophilized product. These include physical appearance, reconstitution time, and quality of the constituted solution, along with residual moisture.

Lyophilized preparations have a unique set of dried finished product attributes in addition to those of liquid, ready-to-use products.^[12] Physical appearance of the dried cake, residual moisture, reconstitution time, and clarity of the constituted solution are product attributes important to quantify. The end result of lyophilization is to preserve attributes the product exhibited when first prepared after reconstitution of the dried product. Validation studies demonstrate and document the capability when starting materials are of a known acceptable quality and an appropriate and well-controlled process is reproduced, the finished product will be of predictable quality, purity, efficacy, and stability. As a minimum, chemical analysis may be used to show that the desired product attributes were preserved during processing and therefore the pro-

cessing conditions were adequate. Measuring the potency of the product is important in verifying that both the filling and freeze drying operations were appropriate and controlled, producing a product with the required efficacy. It is also important to show that any degradation during processing has been avoided. Specific analytical techniques are used to assure this objective has been achieved and the product meets the predefined quality attributes.

The appearance of the dried product, in itself, is not considered a critical product attribute. It does, however, reflect success in processing and finished quality attributes. An objective and a measure of success of appropriate processing conditions is establishing and retaining the quality attributes imparted during freezing. Freeze drying with retention and avoidance of collapse through primary and secondary drying, as described by MacKenzie, reflects the level of success in proper processing.^[13] If appropriate processing conditions are implemented that assure adequate solidification during freezing and the product is maintained below a threshold temperature during primary and secondary drying, the structure established during freezing will be preserved. Product warming above a threshold temperature where the

Dried cake appearance reflects the size and structure of the ice formed during initial freezing. Fig. 5 Dried cake appearance. (View this art in color at www.dekker.com.)

material reverts to a liquid by either exceeding a glass transition causes a collapse of the structure or a eutectic temperature resulting in a melt. Either event alters the structure of the material and affects product behavior during further processing and finished product attributes. A change in the structure may impede sublimation and desorption, resulting in higher residual moisture, as well as influence reconstitution. Any change in the structure of the dried product is detected with physical inspection, assessing the dried cake appearance.

Physical appearance of the dried material can sometimes vary substantially. This is in part dependent upon the nature of the formulation along with techniques used in processing. The appearance of the dried cake is a mirror image of the ice crystal formed during the initial freezing. Fig. 5 illustrates the variation in dried product appearance due to differences in structure resulting from varying ice crystal size. If the ice crystals are large the cake may have a more coarse structure. Conversely, if the ice crystals are small, then the cake structure may be very fine. The structure of the ice is influenced by the shelf cooling rate during freezing. This, in turn, is dependent on the temperature at which the nucleation of ice occurs and on the

rate of ice crystal growth. Searles et al. investigated such influences of cooling rate and effect of thermal treatment on expected differences in ice crystal size.^[14] If the cooling rate is different for the product processed in the manufacturing unit, then the physical appearance may be different.

The physical appearance is not considered a critical product attribute in itself. Rather, the physical appearance, reflecting attributes such as either a coarse or fine structure of the dried cake, may also be associated with other attributes such as reconstitution time. For example, if large ice crystals form during the solidification as the product is chilled during freezing, large voids will remain in the dried product when the ice crystals have sublimed. These large voids then provide an avenue through which the diluent permeates the dried cake upon reconstitution. Changes in cooling rates with a potential effect on ice crystal size and the resultant change in dried product structure may therefore impart differences in ease of reconstitution. A time specification for the dried product to completely go into solution needs to be identified during development.

Ease of reconstitution is a desirable product attribute, although it is secondary to the quality, purity, efficacy,

Visible insoluble material of the constituted solution implicating a physico-chemical change during processing or upon reconstitution.

Fig. 6 Reconstituted solution. (View this art in color at www.dekker.com.)

and stability. Reconstitution will sometimes indicate the presence of material that has collapsed and failed to dry with retention of the structure established during freezing. Collapse and melt back is associated with causing portions of the cake to dissolve more slowly and extend the time required to go into solution completely. The material polymerizing, peptides or proteins forming aggregates, or liposomes coupled or clustered may also be causes of a haze, cloudy solution or insoluble materials during reconstitution. Poorly soluble material or incomplete dissolution similar to that observed in Fig. 6 often indicates that there has been a significant physicochemical change in the product. The end point of the reconstitution is the formation of a clear solution, no less clear than the diluent used for reconstitution.

A target range of allowable residual moisture needs to be correlated to long-term storage stability and is necessary to define during development. Prevention of degradation by hydrolysis is circumvented by the removal of any appreciable water that may become involved in chemical reactions during storage. Stability in the dried state is assessed during development. The residual moisture of the dried product is dictated by the extent of desorption during secondary drying. The rate of desorption is strongly influenced by the product temperature and time in secondary drying. Achieving a residual moisture within the range established in development and correlated to processing conditions verifies that the time necessary for sufficient desorption was adequate when processing the larger batch size.

PROCESS DEVELOPMENT CONSIDERATIONS

There may often be many unknowns about suitable manufacturing operation while in the midst of product and process development activities. For preparation of clinical materials, the product may be produced in-house or at a contract facility. There are multiple possibilities for manufacturing product on a commercial scale: The product may be integrated into an existing in-house operation, manufactured at a yet unidentified contract manufacturing site, or the new product may warrant expansion of an existing operation or construction of a new facility. A direction may well be yet unknown at the time product and process development is ongoing. Such a circumstance requires some assumptions and foresight in selecting parameters when designing a process that would be best suited for routine large-scale manufacturing. Whether a manufacturing site is known or has yet to be identified, and unless there are extraordinary needs dictated by the

product, designing a robust process increases the potential that technology transfer will be successful.

Intending that the process will be suitable for routine manufacturing, an understanding of an existing manufacturing operations capability provides valuable insight, direction, and focus to the development studies. With such understanding, the boundaries and parameters that envelope processing procedures suitable for the current manufacturing operation can be studied in development. If not existing, then an approximation of “typical” capabilities for a manufacturing operation is helpful. With planned expansion of operations required for commercial manufacturing, questions of “What do you need?” and “What can you provide?” for processing capabilities echo between development, engineering, and operations staff. To be complete and comprehensive, the perspective of this presentation on the topic will be development and scale-up into an existing operation. This will at least allow a comprehensive treatment for subjects of interest in scale-up. It is also important to realize that current operations should not necessarily be limited to critical product or processing needs. An example is with the use of organic solvents in a formulation to improve product structure or processing rates.^[15,16] In such circumstances the need of stabilizing the product and impact on the process needs to be weighed in deciding on the direction during development. It is important to also appreciate that the current capabilities of any operation should not stifle creative and beneficial advancements in manufacturing technology.

For the first round of development it is prudent to attempt to fit a product and process within an existing operational capability. The first source of information to seek is the operational qualification (OQ) data quantifying the functional capabilities and performance of the lyophilizer. Table 6 outlines a list of performance capabilities of

Table 6 Performance capabilities from operational qualification studies

interest that allows a sufficient assessment of equipment functions and performance.

Shelf temperature has the greatest influence on the processing rates and ultimate product temperatures at the completion of each process step. The achievable shelf temperature capability ranges from the coldest temperature for freezing to the warmest temperature for primary and secondary drying. High rates of cooling and warming reflect the most aggressive changes in shelf temperature throughout the process. Control capabilities include the variation in controlling at a specific temperature and any relative deviation from the desired set point. This capability can also be influenced by the type and location of the temperature sensor. Shelf-temperature variation influences the batch uniformity and is important at the low temperatures used for freezing, intermediate temperatures often used for primary drying and relatively high temperatures for secondary drying.

Left uncontrolled, chamber pressure reflects the water vapor in transit from the product from which ice is subliming to the condenser where the water vapor is converted back to ice. Chamber pressure has the greatest influence on product temperature. A pressure suitable for a formulation containing sucrose and having a phase transition or collapse temperature of -32°C may be as low as 60 μHg . Preparations with high phase transition temperatures such as those that contain mannitol that tends to crystallize and having a eutectic melt as warm as -2.6°C may be processed using chamber pressures such as 400 μHg . Controlling the chamber pressure during primary drying has been widely used throughout the industry for more than 20 years, as noted previously. The effect and benefit of chamber pressure control during secondary drying is still a controversy.

There are three general methods used to control the chamber pressure. They include injecting nitrogen into the product chamber, injecting air or nitrogen into the inlet of the vacuum pump, and closing the valve between the chamber and condenser or condenser and vacuum pump to decrease the flow of water vapor. It is a common and preferred practice to control the chamber pressure by introducing filtered nitrogen into the chamber using a proportional valve. The behavior of the nitrogen when injected into the chamber, relative effect on rates of sublimation during primary drying as compared to the other methods, influence on desorption during secondary drying, and effect on conversion of water vapor to ice at the condenser surface all need to be considered when utilizing pressure control by the various methods.

Sublimation and condensation rate studies are part of a comprehensive OQ and reflect the capability of the equipment to complete the primary drying. The amount of

ice sublimed from the shelf and collected on the condenser with a constant shelf temperature and chamber pressure indicates the level of performance that can be achieved under load conditions. The rate reflects the capability of the shelves along with the heat transfer system to supply sufficient energy for sublimation. Evolution of corresponding quantities of water vapor challenges the effectiveness and capacity of the condensing system. The quantity of ice sublimed and condensed reflects both the obtainable rates and capacities. Sublimation of ice from the shelves reflects the capability to supply heat to the product. The amount of ice sublimed can also indicate the uniformity when rates from each shelf are compared. For an external condenser the pressure differential between the chamber and condenser reflects any inhibition to water vapor flux because of the equipment configuration when the vapor is in transit from the product to the condenser. The quantity of ice collected on the condenser is a measure of the effectiveness in trapping and removing water vapor and the ability to hold the expected quantity of ice. The sublimation and condensation rate studies are therefore useful in evaluating the equipment capabilities and gaining confidence that the lyophilizer can achieve the required process parameters.

Capabilities of the lyophilizer to be used for larger-scale manufacturing become the extent of processing parameters and therefore provide guidelines for process development studies. For transparent scale-up the parameters investigated during laboratory studies need to be within the known operating capabilities of the manufacturing equipment. Controlling the parameters investigated during process development to within the capabilities of the larger production unit eliminates the need for adjustments to the process when scaling up to larger batches in a manufacturing environment.

Validation data for large-scale processing in manufacturing is also a wealth of information on the processing capability and performance. Historical manufacturing experience with other products provides an indication of the extent of batch-to-batch variation during routine manufacturing. This would include an assessment of both processing capabilities as well as finished product characteristics. The level of control and reproducibility, along with consistency of finished product, can be evaluated to assess capabilities and predict results during scale-up. Batch uniformity with respect to variation that may be attributed to different positions in the lyophilizer included in validation studies can also be useful. Environmental influences and their effect on rates of sublimation relative to position on the shelf have been illustrated by Greiff.^[17] In order to encompass the variation, a sufficiently large batch is necessary to evaluate the impact. As API is often

in limited supply for development studies, a sufficiently large batch may consist of vials filled with only the excipients or use of a surrogate formulation. Realizing that the number of vials in the development study may be small, evaluating the uniformity in behavior during processing and finished product attributes provides insight on the expected variation throughout a larger-scale batch.

Uniformity in the product behavior during processing and consistency in finished product is strongly influenced by nucleation and ice crystal growth during freezing. The randomness of nucleation, an event based on probability, and subsequent ice crystal growth can be a significant influence when solidification is complete during freezing and product temperature during drying. Fig. 7 reflects the distribution of times and temperatures at which nucleation occurs for a limited number of vials within a small-scale batch being monitored using fine-gauge thermocouples carefully positioned in the center at the bottom. Note also the increase in the temperature of the monitored vials reflecting in a second and later increase in temperature due to nucleation and ice crystal growth in neighboring

vials. This delay in the solidification of water in vials without a thermocouple suggests a greater extent in supercooling, imparting the associated attributes expected with smaller ice crystal size. This event occurs with a variation within any group of vials within any single batch. Such variation in nucleation within a group of containers is evidenced with a single batch and therefore within any group of batches. The range is apparent when comparing such events that occur among multiple batches using the same processing parameters. This variation is illustrated in Fig. 8 for four batches of a model formulation chilled using the same parameters.

This variation in product temperatures also occurs during primary drying as drying progresses and reflects what may be considered typical vial-to-vial variation during lyophilization. As ice crystal size dictates the surface area of the remaining solutes there may also be an effect on ease of removing residual moisture in secondary drying. For the same batch illustrated in Fig. 7 above and exhibiting a variation in nucleation, product temperatures will also vary during drying, as apparent in the temperature

Temperature profile during freezing of multiple vials within a batch. Variation in time and range in temperature for nucleation of ice and ice crystal growth for vials monitored using a thermocouple. Increases in temperature following ice crystal growth reflects nucleation and ice crystal growth in vials that do not contain a thermocouple surrounding those being monitored.

Temperature profile during freezing of multiple vials within multiple batches. Variation in time and range in temperature for nucleation of ice and ice crystal growth for vials containing a thermocouple and those not containing a thermocouple surrounding those monitored.

Fig. 8 Variation in time and temperature for nucleation and ice crystal growth within multiple vials of multiple batches. (*View this art in color at www.dekker.com.*)

profile in Fig. 9. This vial-to-vial variation occurs, even in the most carefully controlled laboratory conditions. Such behavior will also occur in routine manufacturing and is important to consider while establishing parameters when developing a process. It is therefore imperative that the process be sufficiently robust to accommodate the inherent variation within a single batch and that occurs from batch to batch.

Compiling the data on equipment capabilities and experience of validation along with routine manufacturing provides a framework in which to select parameters for study during process development. Parameters controlled to within the operational capabilities of the manufacturing equipment minimized any adjustments to the process and continued development efforts during scale-up. Suitable parameters to accommodate variation that may occur within a larger lyophilizer and in routine manufacturing can be considered in the process design during development. Realizing that the product and process will exist in a manufacturing environment for the majority of the product life, the objective of the development studies is to establish a process that will easily integrate into a manufacturing operation during scale-up.

EQUIPMENT INFLUENCES

In circumstances where a new product is being integrated into existing manufacturing operations, the parameters of the process need to be within the manufacturing equipment performance capabilities. Therefore the capability of the equipment used during development and that to be used in manufacturing should be evaluated. This includes equipment design and configuration, control of critical processing parameters, and operating capacities. Understanding how the equipment for development and manufacturing functions and capabilities in implementing the required processing conditions is the first step in transferring a process from one operation to another.

It is not unusual that process development is complete before a manufacturing site is identified. Therefore the guidance for identifying appropriate process parameters for use in manufacturing may not be available. From a manufacturing perspective it is prudent to understand the processing capabilities for the research lyophilizer along with the actual parameters used, as well as any difference on the processing conditions the product experiences. For example, if left uncontrolled during development studies,

Temperature profile and behavior during freeze drying of multiple vials within a batch corresponding to the variation in nucleation of ice and ice crystal growth shown in Figure 7.

Fig. 9 Variation in behavior during processing multiple vials of a single batch. (*View this art in color at www.dekker.com.*)

cooling and heating rates can vary, dependent upon unit manufacturer, equipment component configuration, and lyophilizer capacity. When transferring a process, the processing conditions specified during development need to be replicated in routine manufacturing. Typical capabilities of the development unit that are important to assess are the same as those when evaluating large-scale manufacturing equipment, as presented in Table 5. Other considerations are instruments and methods used for process control and monitoring. A suitable production lyophilizer utilizes a resistance temperature device (RTD) located in a thermowell positioned in the heat transfer fluid just prior to where the fluid enters into the chamber and is the control point for the shelf temperature. This location is the most effective to use for control, as it provides the most consistent measurement, accommodating dynamics of the equipment, variations in processing, and differences in thermal load. Research units may have the sensor in a different location or a different method for monitoring and controlling the shelf and implementing temperature control. The impact of such a difference is the level of control as well as an offset to the actual shelf temperature. For example, an RTD located in a heat transfer fluid storage tank that is located upstream of the refrigeration heat exchanger and heater

would reflect different dynamics and therefore a different “shelf” temperature.

A second major variable is method of pressure measurement. Research units often use thermoconductivity type pressure instruments to monitor the chamber pressure. These instruments were designed for measuring processes conducted at reduced pressures, such as those in the electronics industry. These instruments measure the differences in thermoconductivity of an atmosphere within the lyophilizer. Given the ideal gas law where $PV = nRT$, the pressure decreases with a decrease in n , the number of molecules, where the molecular density, the number of molecules per unit volume is reduced, with all other variables constant. The thermoconductivity of an atmosphere decreases with a decrease in the molecular density and can be correlated to pressure. As these instruments are calibrated against nitrogen, the main constituent of a normal atmosphere, when sensing the pressure of a different atmosphere, such as that composed of water vapor, these types of instruments will indicate a different pressure. These instruments are prone to errors when the composition of the atmosphere varies. Sublimation during primary drying yields a composition of the atmosphere in the chamber high in water vapor, resulting in errors in measure pressure as high as 60%.

Position of the sensor can also have an influence on the indicated pressure. Monitoring and control of the pressure that comprises the environment to which the product is exposed is necessary. Therefore the sensor needs to be positioned on the product chamber. If the sensor is positioned on the condenser vessel or in the piping going to the vacuum pump, then the measured pressure will not reflect the amount contributed by the water vapor present during the sublimation of ice. Research lyophilizers sometimes have the pressure sensors located on the vacuum line and actually read the pressure of the pump rather than the chamber.

EXECUTING SCALE-UP ACTIVITIES

Knowledge of manufacturing capacities and capabilities, appropriate and adequate processing conditions for a robust process, coupled with careful control of starting material and processing conditions are necessary for successful technology transfer in achieving the predefined processing conditions and predicted finished product qualities. Sufficient knowledge of the product and process gained in development prevents scale-up from becoming a period of discovery. Processing at larger batch sizes provides an opportunity to verify the suitability of the processing parameters identified during development and focus on assessing the distribution of behavior and uniformity of finished product qualities at a larger scale.

A complete and comprehensive development report is an invaluable resource for technology transfer. This document preserves the body of knowledge and experience gained during product design and process development activities. Information including characteristics of the API, formulation, and finished product outlined in the preceding sections are part of a comprehensive development report. As well, the knowledge and experience in initial scale-up for processing clinical material is also valuable. The expected behavior, finished product attributes, and any difficulties that arise in scaling-up provide useful insight as larger batch sizes are integrated into routine manufacturing.

Realistically, subtle differences between conditions and outcomes during development and those in large-scale manufacturing will exist. Influences of preparing a product and processing in a manufacturing environment, in conjunction with the expanded quantity of finished product, combine to become significant factors. Batch sizes and quantities of finished units are often nominal as compared to that of large-scale manufacturing. Development studies and early clinical manufacturing requirements may only require relatively small batch sizes. As such, if the incidence of an event or result is one in a

thousand and the batch size is a few hundred vials, it may only be an occasional observation or result. If the frequency is one in a few thousand, it may not become evident until large-scale batches are prepared in manufacturing. With manufacturing batch sizes approaching as large as tens of thousands of units being common, a statistically small incidence becomes a meaningful quantity of finished product.

The statistical distribution of variables simply due to larger quantities of finished product units will all be factors. These factors can be compounded such that any one alone has little or no impact. In combination and with potential of synergistic effects, the outcome of scale-up may yield results that are beyond any previous experiences. The level of success, even with factors or influences that may not be foreseen, is strongly dependent on the extent of knowledge and preparation during development as well as refinements implemented during the steps in preparation of clinical materials, leading up to integrating a new product into routine manufacturing for supplying the marketplace.

For scale-up of the lyophilization process, critical process parameters of shelf temperature, chamber pressure, and time are compared to those established during development and intended to be implemented using a larger lyophilizer. Some reasonable variation due to the dynamics of larger size and capacity equipment would be expected. For example, there may be an initial overshoot for a short duration when changing processing parameters. This is typical of proportional type control, where the amplitude and frequency of oscillations around the set point decreases until constant control at the set point is achieved. Proportional control is used for both shelf temperature and chamber pressure. These oscillations may be observed at the completion of a ramp leading to a controlled shelf temperature at a specific set point or when changing chamber pressure control, as in the transition from primary to secondary drying. These oscillations, if they are of nominal extent and duration, have little, if any, effect on product temperature during the process. Product during freezing and drying may also exhibit different behavior. Placement of product temperature sensors is a major influence. Precise placement is relatively easily accomplished in a development laboratory setting. Using good aseptic technique in processing sterile product limits the manipulation necessary for specific placement of a sensor in a vial. Even with such difference in placement, accurate temperature values are assured at the most critical times in the process; the end of loading, freezing, primary, and secondary drying. It is important to verify the product has reached critical temperatures at the end of each of these steps to assure the conditions are adequate before progressing to the next step. Verifying that the

product is chilled below the phase transition temperature and maintained below the threshold temperature identified during development are important assessments in evaluating the product temperature profile during scale-up batches.

Product behavior for a sterile product in manufacturing is also influenced by the conditions imparted due to requirements for aseptic processing. Materials prepared under laboratory conditions in a development environment are typically processed differently than in a manufacturing environment. For example, the level of cleanliness and bioburden are different. Product attributes, such as the nucleation and crystal growth of ice, would occur at different temperatures and rates. This has an influence on product behavior during processing and finished product attributes, as discussed earlier.

Verifying processing conditions are suitable and within reasonable range, finished product attributes are assessed and compared with expected results. Attributes associated with lyophilized preparations such as physical appearance, reconstitution, and residual moisture are important to evaluate and compare differences between results from development studies and those in a manufacturing environment. In addition, potency and purity, along with those attributes specific to a lyophilized dosage form, are compared to the specifications identified during development and refined as clinical studies progress.

Processing a larger number of units as batch sizes increase provides an opportunity to evaluate process capability. Beyond evaluating processing conditions and finished product attributes processed in a manufacturing environment, larger-scale batches provide an opportunity to evaluate the process dynamics and resulting product on a larger scale. It is prudent to evaluate a larger number of product samples during the initial large-scale manufacturing as compared to the relative limited number samples during routine manufacturing. With a larger number of samples, statistical methods provide a greater capability of quantifying the variation in product characteristics and quality attributes. Kieffer and Torbeck present methods and illustrations of establishing sample size and statistical approaches in conducting process capability studies using a step-by-step procedure useful for statistical evaluation when scaling up to larger batch sizes.^[18] When processing larger batch sizes, reproducibility of processing conditions can be coupled with evaluating batch uniformity. This may include randomized sampling of a larger number of finished product units and using statistical methods to compare results within some desired distribution. Use of statistical methods provide a more quantitative measure at a larger scale for each scale-up batch and evaluate the results achieved between batches. This leads to accomplishing a higher degree of assurance as the product moves

toward integrating the production into commercial manufacturing.

CONCLUSION

Ease and success of scale-up depends on the knowledge and experience gained beginning with development. Scaling up as the product progresses from development, through clinical studies, ultimately to large-scale commercial manufacturing occurs in multiple steps. During this progression there are often refinements to the product and process along the way. The starting materials should be well characterized. This includes the quality and purity of the API, adjustments in API, and formulation excipient concentrations, as well as the container-closure components. Requirements for preparing a batch and accommodating any product sensitivity need to be well defined for assuring the quality of the starting solution. A sufficiently robust process, with target parameters identifying "ideal" conditions, along with definition of a proven acceptable range within boundary conditions needs to be readily executed within a manufacturing environment.

The statistical distribution of variables due to larger quantities of finished product units can become a significant influence factor. This factor may be compounded such that any one alone has little or no impact. In combination and with potential of synergistic effects, the outcome of scale-up may yield results that are beyond any previous experiences. The level of success, even with factors or influences that may not be foreseen when preparing for scale-up in manufacturing as batch sizes increase, is strongly dependent on the extent of knowledge and preparation during development. This is also influenced by the extent of refinements implemented during the steps in preparation of clinical materials, leading up to integrating a new product into routine large-scale manufacturing.

Gelatin-Containing Formulations: Changes in Dissolution Characteristics

Saranjit Singh
Sariputta P. Pakhale

National Institute of Pharmaceutical Education and Research, Nagar, India

INTRODUCTION

Dissolution parameter or the dissolution profile is one of the important specifications for oral solid dosage forms. Even during aging, dissolution characteristics are required to remain either unchanged or within specifications laid down with reference to the results observed during bioequivalence, comparative bioavailability, or clinical studies. The product can be rejected and recalled if dissolution instability is shown during storage under conditions defined on the label. In that respect, the manufacturer of a pharmaceutical product has a responsibility not only from ethical, moral, and legal standpoints, but also for economical reasons to ensure that the drug is released reproducibly from the dosage form during the shelf life.

The problem of alteration in dissolution characteristics on aging is typical to gelatin-based dosage forms. It is routinely faced by the manufacturers and, therefore, is a matter of concern. Fortunately, a lot of understanding has been developed over the period, since the time the problem was first recognized. The purpose of this article is to put the problem in the right perspective based on recent developments and the review of the reports in literature.

THE PROBLEM OF PELLICULIZATION

Gelatin is hydrolyzed by most of the proteolytic systems to yield amino components. Further, it reacts with acids and bases, aldehydes and aldehydic sugars, anionic and cationic polymers, electrolytes, metal ions, plasticizers, preservatives, and surfactants. Even, exposure to stress conditions of humidity, temperature, and/or light leads to perceptible changes.

The exposure of gelatin formulations to environmental factors and/or chemical catalysts results in formation of a swollen, very thin, tough, rubbery, water-insoluble membrane, also known as "pellicle." This membrane acts as a barrier and restricts the release of the drug. It is

not disrupted easily by gentle agitation and as a result dissolution characteristics of formulations containing gelatin in the outer layer change and Q -values often drop to the point of rejection.^[1,2] An example is shown in Fig. 1.^[3] The plot depicts a comparison of dissolution behavior of fresh gelatin capsules against 1-yr old capsules and tablets devoid of gelatin. Evidently, 1-yr old capsules show reduced dissolution rate, in particular.

Fortunately, several studies have shown that the problem of fall in dissolution rate of gelatin formulations has a little consequence on in vivo drug bioavailability.^[4–6] Fig. 2 depicts both dissolution and bioavailability profiles for fresh drug capsules and those stored at room temperature for 11 mo.^[7] It shows a drop in in vitro dissolution by ~50% (Fig. 2a), but no significant change in C_{\max} or t_{\max} values (Fig. 2b).

The absence of in vivo effect is attributed to digestion of the denatured gelatin by enzymes present in GIT. This is the reason that the problem was not even exposed before 1960s when simulated gastric and intestinal fluids were used as dissolution media. There are large numbers of studies in literature, which have shown that adverse effects on dissolution are virtually eliminated when the products are tested in the dissolution media containing enzymes.^[8–12] An example highlighting the corrective influence of enzymes on reduced dissolution of stressed ibuprofen hard gelatin capsules is shown in Fig. 3.

The studies of the type shown in the figure indicated that if enzymes were able to alleviate the impeding barrier exerted upon the drug molecule by highly cross-linked gelatin capsule wall, so a dissolution test in the presence of enzyme could avoid the time and cost of bioequivalence studies. Accordingly, attention was called on having a two-tier dissolution test for specific evaluation of gelatin products.^[12] The test was eventually developed by a FDA's Industry Gelatin Capsule Working Group in which USP was also a participant. It was included in the 25th edition of USP.^[13] The test encompasses initial dissolution study in the plain medium as specified in the individual monograph, followed by a second dissolution in the medium containing enzymes. Two types of enzymes,

Gelatin-Containing Formulations: Changes in Dissolution Characteristics

Fig. 3 Release profiles of fresh hard gelatin capsules (■) and those stored for 8 day at accelerated conditions of 40°C/75% RH in the presence of light (□, ◆). It is evident that dissolution rate improves in the presence of enzyme.

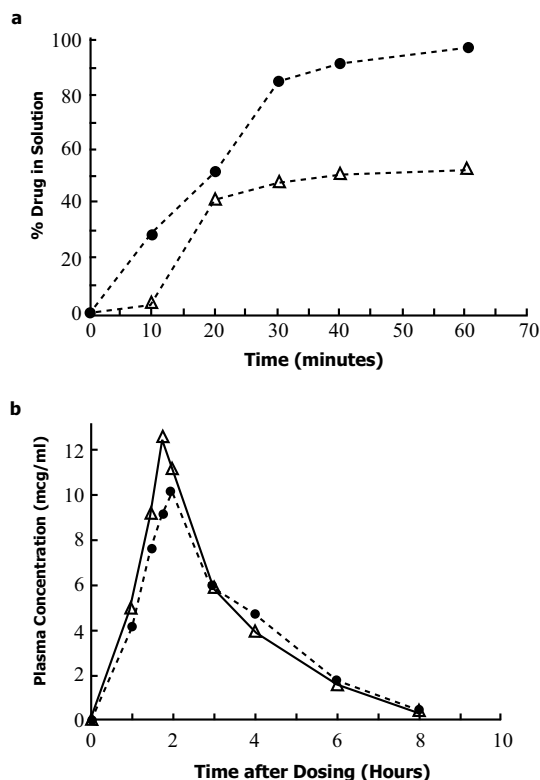

Fig. 2 Comparison of dissolution (a) and bioavailability (b) of capsules containing a high dose hydrophobic drug. Key: ●, fresh capsule; △, capsules stored for 11 mo at room temperature. The plot shows that while dissolution is affected on prolonged storage, there is no corresponding change in bioavailability profiles. (From Ref. [7], p. 16, by courtesy of Wiley-Liss Inc., a subsidiary of John Wiley & Sons Inc.)

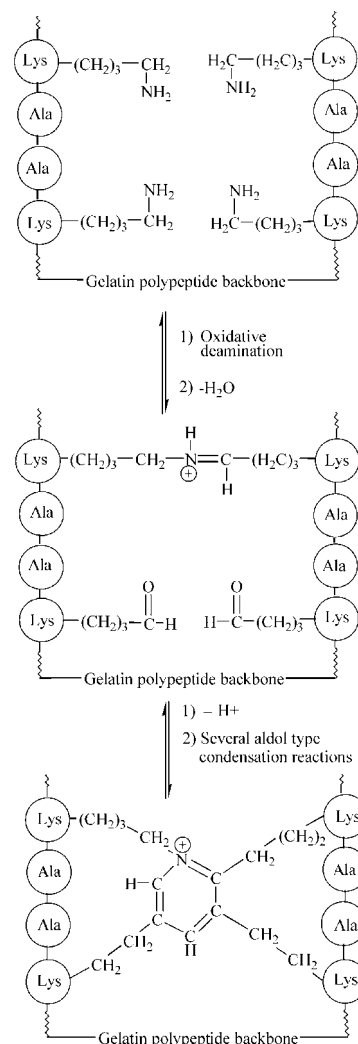

Fig. 4 Cross-linking reaction involving free amino groups of lysine. (From Ref. [1], p. 916. Reprinted by courtesy of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.)

pepsin and pancreatin, are recommended, depending upon the pH of the dissolution medium. Purified pepsin resulting in an activity of 750,000 units or less per 1000 mL is suggested for the conditions where a monograph recommends water or a medium with a pH less than 6.8. For the medium with pH of 6.8 or greater, pancreatin is added at not more than 0.05 g per 1000 mL. Efforts currently are directed towards extension of the USP two-tier test to formulations containing insoluble drugs for which the use of nonionic surfactants combined with pepsin has been explored.^[8]

Nevertheless, the problem of pellicle formation and eventual fall in dissolution rate is still of concern, as the drug bioavailability may be influenced if there is a severe challenge. There is a report where exposure of phenytoin capsules to high humidities resulted in poor dissolution as well as destruction of clinical efficacy.^[14] Moreover, the enzyme test is not official in pharmacopoeias other than USP and the products stand a chance of being recalled, if the normal pharmacopoeial dissolution limits are not met.

THE CHEMISTRY OF PELLICLE FORMATION

Gelatin is a mixture of water-soluble proteins derived from collagen. It is a linear polymer with molecular weight ranging between 15,000 and 250,000. The protein fractions consist of variety of amino acids joined together by an amide linkage. The amino acids include glycine 25.5%; proline 18.0%; hydroxyproline 14.1%; glutamic acid 11.4%; alanine 8.5%; arginine 8.5%; aspartic acid 6.6%; lysine 4.1%; leucine 3.2%; valine 2.5%; phenylalanine 2.2%; threonine 1.9%; isoleucine 1.4%; methionine 1.0%; histidine 0.8%; tyrosine 0.5%; serine 0.4%; cystine 0.1%; and cysteine 0.1%.^[1] The pellicle formation is attributed mainly to trifunctional amino acids, especially lysine. Some reports have also suggested involvement of histidine and arginine.

The changes take place through three main mechanisms.^[1] First is the oxidative deamination of lysine residues, which are proximal to each other, resulting in terminal aldehyde groups. The aldehyde groups combine with free ϵ -amino group of a neighboring lysine to yield

Fig. 5 Cross-linking reactions of gelatin mediated through cationic imine formation. (From Ref. [1], p. 917. Reprinted by courtesy of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.)

an imine, which subsequently undergoes a series of aldol type condensation reactions to produce a cross-linked product containing pyridinium ring(s). This mechanism is described in Fig. 4. The second mechanism involves reaction of the lysyl ϵ -amino groups with an external aldehyde, present in the formulation as an impurity or generated in situ on exposure of formulations to adverse environmental conditions. This reaction yields a hydroxymethylamino derivative, which loses water to form a cationic imine. The latter reacts with another

hydroxymethylamino lysine residue to form dimethylene ether, which eventually rearranges to form a methylene link between two lysyl ϵ -amino groups, resulting in development of a cross-link. The third mechanism is the formation of an aminal, the amine form of an acetal, which is generated on reaction of cationic imine intermediate (see upper point) with a free amino group. The pH of surroundings plays an important role in this reaction. The last two mechanisms are depicted in Fig. 5.

Fig. 6 Cross-linking through formation of interstands and intrastands bridges across polypeptide backbone. (From Ref. [1], p. 918. Reprinted by courtesy of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.)

The cross-linking of the gelatin polypeptides may occur either through bridging within the same polypeptide strand (intrastrand, intramolecular cross-linking) or between amino acid residues from two neighboring peptide strands (interstrand, intermolecular cross-linking).^[1] The formation of strands is shown in Fig. 6. As a result, the interparticulate bonds formed in the original compact are removed and replaced by new bonds resulting in the dosage form that has different porosity and pore structure. Hence different in vitro release pattern is obtained as compared to the original.^[17]

TYPE OF GELATIN PRODUCTS THAT SHOW CHANGES IN DISSOLUTION BEHAVIOR

The altered dissolution behavior due to pelliculization occurs mainly in those products that contain gelatin in the outer layer. Typical dosage forms are hard and soft gelatin capsules and sugar-coated tablets.

Table 1 lists some of the examples where dissolution problems have been reported with hard gelatin capsules. Fig. 7 depicts the behavior in one such case. Hard capsules normally contain ~13%–16% water, which acts as a plasticizer and imparts flexibility. The moisture variations in the range of 12%–18% do not seriously impair the shell structure, however, below 12%, the shells become brittle and get easily ruptured. The capsules become moist, soft, and distorted when the moisture rises above 18%. Even otherwise, moisture can be transferred from shells to deliquescent and hygroscopic contents or the reverse flow of moisture can result from contents to shell in case of efflorescent ingredients, causing potential softening and sticking of the capsules. The transfer of moisture between capsule contents and the shell is proposed to be one of the reasons for changed properties and eventual retardation of drug release.^[22] For example, Geogarakis, Hatzipantou, and Kountourelis^[23] observed a significant retardation in dissolution rate of ampicillin trihydrate hard gel capsules on storage under varying humidities (50%–90% RH).

Table 1 Literature reports on changes in dissolution characteristics of hard gelatin capsules

Drug	Storage conditions				Effect on Dissolution	Reference
	Temperature (°C)	% RH	Illumination	Time period		
Gemfibrozil	37	—	—	1 mo, 2 mo, and 3 mo	—	5
Poorly water soluble drug	37	80	—	On-going stability study	Significant ↓ at 1 mo	8
	45	—	—		—	
Etodolac	40	75	—	8–20 weeks	Significant ↓ in all	15
	40	75	—		Significant ↓	
Chloramphenicol	25	49	—	32 weeks	No change	16
		66			No change	
		80			No release up to 1 hr	
Nitrofurantoin	40	79	—	2 and 10 weeks	Significant ↓ in 10 week samples	17
Hydrophobic drug in various colored capsules	—	80	Ambient light	2 weeks	Significant ↓	18
		80	Fluorescent	2 weeks	Significant ↓	
Hydrophobic drug in clear capsules	—	80	UV	2 day	Significant ↓	
		80	Ambient light	4 weeks	No change	
Triamterene/hydrochloro-thiazide	40	85	Fluorescent	4 weeks	No change	19
		85	—	4 weeks	Significant ↓ for both drugs	
Acetaminophen	40	75	—	55 day	Significant ↓	20
	25	60	—	52 weeks	Significant ↓	
Hard gelatin capsules shells	81	37	—	12–14 weeks and 21 weeks	Significant ↓ in all	21

↓ = Decrease in dissolution.

RT = Room temperature.

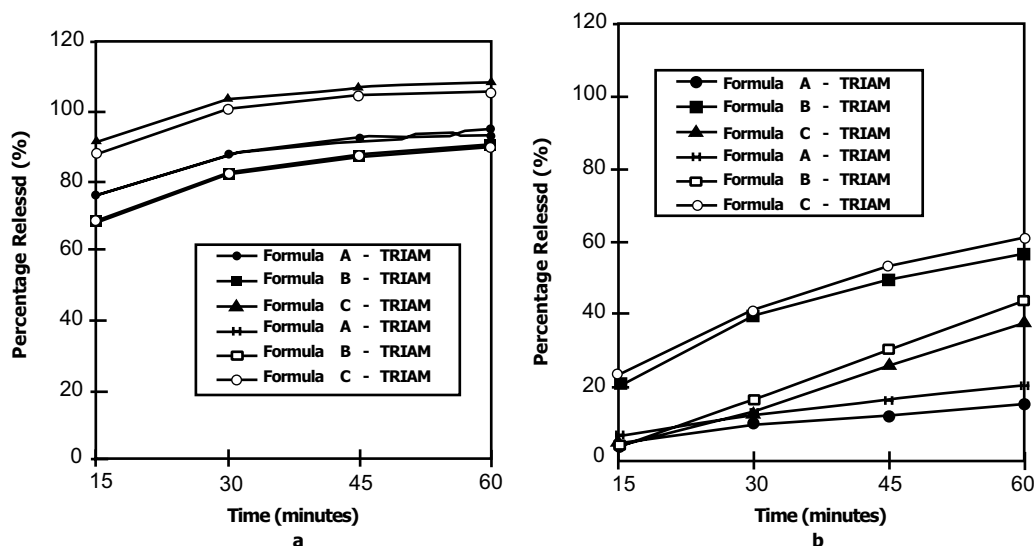

Fig. 7 Dissolution profiles of hard gelatin capsule formulations, three each containing triamterene (TRIAM) and hydrochlorothiazide (HCTZ). Key: Fresh capsules (a); and capsules stored at 40°C/85% RH for 4 weeks (b). Formula A is control, Formula B contains glycine, and Formula C contains citric acid. Comparison of the two figures clearly shows fall in dissolution on exposure of all formulations to high temperature and humidity conditions. (From Ref. [19], p. 497 by courtesy of Marcel Dekker, Inc.)

The observed behavior was attributed to the agglomeration and subsequent caking of the capsule contents due to moisture transfer from the shell.

The reports from literature on dissolution problems with soft gel capsules are summarized in Table 2. Soft-shell capsules, like hard capsules, are also influenced by environmental and chemical factors, but the extent of pelliculization is higher due to a larger mass of gelatin in soft capsules.^[30] This is well projected in Fig. 8. The plot gives a comparison of release profiles of amoxicillin

trihydrate from hard and soft gelatin capsules exposed to similar type of storage conditions.^[29] Evidently, soft gel capsules show more severe change. Under high humidity, soft capsules become soft, tacky, and bloated, offering a possibility not only of migration of moisture from shell to capsule contents, but also of reverse flow of chemical catalysts, when present in solvents used in preparation of drug solutions or dispersions. The shells of soft capsules also contain plasticizers, typically glycerine or sorbitol, PEG, and ethers of polyethylenated glycosides, along with

Table 2 Literature reports on changes in dissolution characteristics of soft gelatin capsules

Drug	Storage conditions			Time period	Effect on dissolution	Reference
	Temperature (°C)	% RH	Illumination			
Acetaminophen	40	75		55 day	Significant ↓	20

Gelatin-Containing Formulations: Changes in Dissolution Characteristics

7

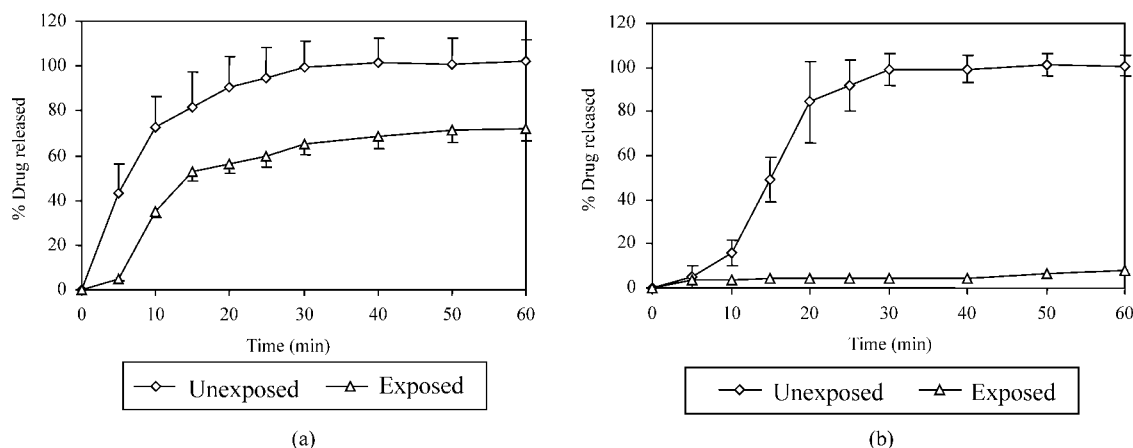

Fig. 8 Release profiles of hard (a) and soft gelatin (b) capsules of amoxycillin trihydrate in unexposed condition and after exposure to 40°C/75% RH/light for 8 day. The soft gelatin capsules show more drastic fall in dissolution upon exposure than the hard gels.

gelatin and water and any catalytic impurities present in these materials can also contribute to chemical and dissolution instability.^[31,32]

Table 3 gives a summary of the known dissolution problems with sugar-coated tablets. The progressive decrease in disintegration and dissolution has been ascribed to adherence of gelatin subcoat to the tablet core.^[33] This was also a conclusion made in a study where most of the core tablets were found to be dry even at the end of the dissolution test.^[34] Fig. 9 shows an example of sugar-coated chloroquine phosphate tablets exposed to 40°C and 75% RH. Clearly, the dissolution rate decreases with time.^[12]

There also exists a report in literature on increase in both disintegration and dissolution time even in tablets containing gelatin as a binder. This happened when tablets were stored at 50°C/83% RH and 70°C/96% RH for 7 weeks.^[37] However, not much decrease in dissolution was observed in another study, when similar dosage form was

stored under milder condition of 40°C/75% RH and light for 3 weeks.^[38] It shows that pellicle formation may occur even in other gelatin-containing dosage forms, when exposed to severe storage conditions. Further, it confirms the contention that the problem of pellicle formation is an easy occurrence in dosage forms containing gelatin in the outer layer.

In one of the studies, sensitive gelatin dosage forms were also evaluated for the extent of cross-linking in the packaged form.^[29] Fig. 10a–c depicts the behavior of dissolution of hard and soft gelatin capsules in blisters, after exposure to accelerated conditions of temperature and humidity in a photostability chamber. The data for fresh and unpacked formulations are also included for comparison. Fig. 10a shows no significant change in the dissolution of packed amoxycillin trihydrate hard gelatin capsules as compared to the unexposed product, while the dissolution evidently is delayed in case of directly exposed capsules. The behavior of two soft gelatin

Table 3 Literature reports on changes in dissolution characteristics of sugar-coated tablets

Drug	Storage conditions				Effect on dissolution	Reference

↓ = Decrease in dissolution.

RT = Room temperature.

Fig. 9 Release of chloroquine phosphate from marketed sugar-coated tablets on storage at 40°C and 75% RH up to 20 day. Evidently, the dissolution rate falls with increase of the duration of storage under accelerated conditions of temperature and humidity.

capsules in blisters (Fig. 10b and c) shows that changes in dissolution, from minor to complete, occur in packed formulations as compared to unexposed samples. The unpacked capsules of course undergo drastic changes. The comparison of the three figures confirms the previous contention that soft gels are more severely cross-linked than hard gels, and it additionally shows that blister packs may provide complete to nil protection, depending upon the drug and the nature of capsules, whether hard or soft. The release profiles of trifluoperazine sugar-coated tablets packed in strip packaging (Fig. 10d) show that the release of the drug from both the strip-packed and unpacked tablets is delayed by around 20 min, after which the profiles merge with those of the unexposed samples. The lag period perhaps appears out of the influence of temperature, as strips are expected to be impervious to both humidity and light.

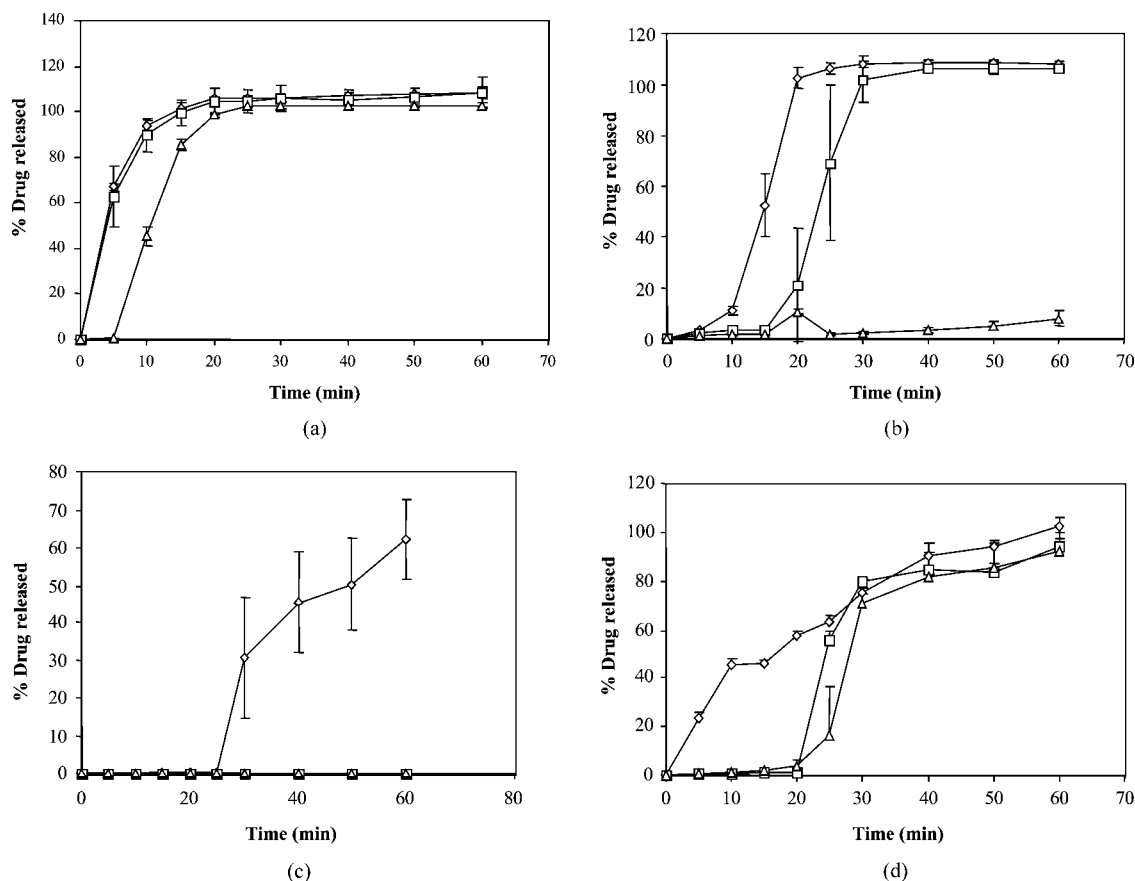

Fig. 10 Release profiles of hard gelatin capsule containing amoxicillin trihydrate (a); soft gelatin capsules containing cephalixin (b); soft gelatin capsules containing nimesulide (c); and sugar-coated tablets containing trifluoperazine (d) upon storage at 40°C/75% RH in the presence of light.

FACTORS INDUCING THE CHANGE

Tables 1–3 and Figs. 1, 2a, 3, 7b, and 8–10 show that a significant fall in dissolution can take place in gelatin formulations, when exposed to normal or accelerated environmental conditions of temperature, humidity, and/or light for varied durations. It clearly means that the pellicle formation is catalyzed by environmental factors, either alone or in combination.

The cross-linking reaction is normally slow at room temperatures, and it may take several weeks or even months before a perceptible change is observed. High temperature accelerates pellicle formation through the process of denaturation by increasing the rate of cross-linking reactions and a typical example is depicted in Fig. 11.^[25] The pellicle formation is also accelerated when high humidity is combined with high temperature. Humidity plays an independent role, influencing pellicle formation in several ways, like indirect catalysis of imine formation, catalysis of excipient decomposition yielding products, which cause cross-linking of gelatin, and as a vehicle for denaturation of gelatin. The rate of cross-linking is further influenced by UV and visible irradiation, when combined with humidity^[18] or humidity and temperature.^[38]

Apart from the environmental factors, chemical compounds also induce cross-linking of gelatin. Supporting this is the mechanism in Fig. 5, which highlights the role of external aldehydes. Among the low molecular weight aldehydes, formaldehyde is most important as it is released in dosage forms from plasticizers and preservatives, fats, and polyethylenated compounds such as PEG, ethers of PEG, and aliphatic alcohols or phenols, polyethylenated glycerides, nonionic surfactants (polysorbates, esters of unsaturated fatty acids), and corn starch.^[4–6,39,40] The corn starch at times contains traces of stabilizer hexamethyl

tetramine, which decomposes under humid conditions to form ammonia and formaldehyde.^[4] Accordingly, a lot of work has been done to establish correlation between the concentration of formaldehyde and the extent of reduction in dissolution of gelatin-containing preparations.^[21,41–44] Other aldehydes reported to influence integrity of gelatin include furfural, acrolein, glutaraldehyde, and glyceryl aldehyde.^[1,5,6,19,27,45,46] An interesting case is the negative effect on the dissolution rate of gelatin capsules in the presence of rayon coiler, which is filled in the headspace of HDPE bottles containing capsules.^[45,47] The rayon produces furfural, which when present in saturated vapor phase, rapidly insolubilizes gelatin capsules. The reported effect is depicted in Fig. 12.

There are several other chemicals, which induce pelliculization of gelatin. These are saccharides, e.g., glucose and aldose sugars^[11]; imines and ketones^[21]; dyes like FD&C red No. 3 and 40^[10,48]; hydrogen peroxide, benzene, sulfonic acids, *p*-toluene sulfonic acid^[19,49]; carbodiimides, e.g., 1-ethylene 3-(3-dimethylamino propyl) carbodiimide hydrochloride, guanidine

Fig. 11 The behavior of dissolution of gelatin shell with time at different temperatures. hydrochloride^[19,46]; terephthaloyl chloride^[50]; and calcium carbonate.^[51,52]

INDUCTION OF PELLICLE FORMATION

It is always desirable to have some sort of preassessment whether dosage forms containing gelatin would show a decrease in dissolution rate due to pellicle formation with time on storage. Sometimes, the formulations are also intentionally subjected to stress conditions to judge the efficacy of enzymes in the dissolution medium for their capacity to overcome pellicle formation. For this purpose, a few approaches have been used successfully.

One example is the addition of formaldehyde at concentrations of 0 ppm, 20 ppm, 80 ppm (or 120 ppm) in lactose and filling of this material in soft and hard gel capsules.^[20,21,27,53] Formulations, so prepared, are stored at room temperature and/or accelerated conditions of 40°C and 75% RH. The samples are drawn at various times and subjected to dissolution in plain and enzyme containing media. Comparison of results gives an idea on the susceptibility of the formulation towards pelliculization. However, one disadvantage of this method is that at times notable retardation of drug dissolution occurs only after storage of the product at room temperature/accelerated conditions for several days or months.^[20,27,30] The long period of storage prevents carrying out of repeated trials, particularly during formulation and packaging development.

A better, versatile, and rapid method is the preparation of films of raw gelatin material (according to the formula for hard or soft gelatin capsules) and exposing small

pieces to formaldehyde vapors in a closed chamber for 12 hr. The set up and conditions were described in a recent report.^[43] Some workers also use a dipping method to expose gelatin film to aldehyde.^[26,50,54] The major advantage of the direct formaldehyde exposure methods is that it takes shorter time, of only a few hours. The method was used recently for classifying raw gelatins in order of their sensitivity to cross-linking.^[43]

Another method, which also gives similar results, involves simultaneous exposure of gelatin films to all the three environmental factors, viz., temperature, humidity, and light. The films or pieces are exposed for 8 day in a photostability chamber at 40°C/75% RH, with a total illumination of 2 million lux hr visible light and UV light of $>200 \text{ W hr m}^{-2}$.^[43] The samples are withdrawn and subjected to dissolution studies. Although the test takes 8 day, the major advantage of this test method is that it simulates the environmental conditions, to which the product is expected to be exposed during its manufacturing, transportation, distribution, and storage. Another benefit is that formulations can be directly studied in unpacked and packed state.

EVALUATION OF THE EXTENT AND NATURE OF CROSS-LINKING

There are several ways to investigate the extent and nature of cross-linking undergone by gelatin and its products as a consequence of exposure to environmental factors and chemical catalysts. Table 4 provides the list of methods and their applications.

A simple method to determine the extent of gelatin cross-linking is the determination of the solubility of

Table 4 Methods for the determination of the extent and nature of cross-linking in gelatin films and formulations

Technique	Application
Monitoring of solubility and dissolution	Determination of the extent of cross-linking
Gravimetric analysis, a protein assay method (involving color reaction with bicinchoninic acid) and UV absorbance measurements at 214 nm	Determination of the extent of noncross-linked gelatin
Chemical analysis using TNBS reagent	Loss of ϵ -amino groups upon cross-linking
Fluorescence spectrophotometry	Conformational changes of gelatin in gel state
¹³ C-NMR spectroscopy	Determination of the types of cross-links developed during reaction with formaldehyde
FT-Infrared (FT-IR) spectroscopy	Determination of the types of cross-linking
FT-Near Infrared (FT-NIR) spectroscopy	Determination of water uptake by the dosage form, extent of cross-linking and monitoring of migration of formaldehyde from contents to the shell
Magnetic Resonance Imaging (MRI)	Study of diffusion of ions into the gelatin–water matrix

the films or dissolution of formulations.^[43,55] The fall in solubility/dissolution has been shown to be linearly correlated to the extent of cross-linking.^[43] Thus a good idea on the extent of change undergone by films or formulations at any time under the specific challenge can be obtained from these simple tests. There also exist some indirect methods like gravimetric analysis, a protein assay method (involving color reaction with bicinchoninic acid), and UV absorbance measurements at 214 nm to determine gelatin in the dissolved or an undissolved state.^[21,56] A furthermore in-depth study can be done by the use of a chemical assay employing 2,4,6-trinitrobenzenesulfonic acid (TNBS).^[21,46,54,56] The reagent reacts with primary amino groups of gelatin and helps to know the loss of ϵ -amino groups, which participate in the cross-linking process.

Determination of intrinsic fluorescence can be used to investigate conformational changes undergone by gelatin gels.^[57] On the other hand, the mechanism and site of development of cross-links can be studied by the use of ¹³C-NMR spectroscopy. This technique has been successfully used for the determination of the involvement of amino groups in lysine-lysine, lysine-arginine, and arginine-arginine cross-links, subsequent to reaction with formaldehyde.^[58-61] Using the same method, Gold, Smith, and Digenis^[59] established that pancreatin, a proteolytic enzyme present in the gastrointestinal tract, depolarizes cross-linked gelatin. Some workers have also explored the use of FT-IR and FT-NIR spectroscopy. Salsa, Pina, and Teixeira-Dias^[62] employed FT-IR for the determination of the types of cross-links developed during reaction with formaldehyde. The FT-NIR spectroscopy was used for the determination of water uptake,^[63] extent of cross-linking, and for monitoring migration of formaldehyde from capsules contents into the gelatin shell.^[41] The combination of NIR spectroscopy with principal component analysis, a multivariate analysis, was found to give good predictable results.^[41,63] Recently, Magnetic Resonance Imaging (MRI) has been found suitable for the study of diffusion of ions into the gelatin-water matrix and the setting of gelatin on cross-linking.^[64]

APPROACHES FOR THE DEVELOPMENT OF STABLE GELATIN FORMULATIONS

Looking into the wide-spread use of gelatin-containing dosage forms and the commonality with which the problem of cross-linking or pellicle formation is observed, there exists a good deal of interest in developing stable formulations that would not show problem of reduced dissolution with time. The solutions, of course, lie in

countering the influence of environmental and/or chemical catalytic factors, discussed above.

The simplest approach is the use in formulations of gelatin grades that are resistant to the influence of environmental factors as well as chemical catalysts. Such gelatins are sold commercially. The enquiry about the resistance of the gelatin raw material to cross-linking should be made from the manufacturer/supplier before purchase of the material. Generally, gelatins with bloom strength lower than 250 are less prone to pellicle formation and there exists no difference with respect to cross-linking among the types A and B of gelatins.^[65]

Otherwise, the appearance of problem due to exposure to accelerated and stress environmental conditions (Tables 1-3) can largely be overcome by storing dosage forms containing gelatin in the outer layer under cool, dry, and dark conditions. Instructions in this regard can be added on the labels of the gelatin-based products. The manufacturers at their level can help control the problem by paying particular attention to moisture, as it induces pellicle formation in a variety of ways. The humidity is required to be controlled even during the manufacture of gelatin-based formulations. The products should also be packed in moisture and light resistant packaging. For example, the stability of products packed in blisters can be improved by the use of water-impermeable films and laminates, like polyvinyl chloride (PVC)-polyvinylidichloride (PVDC), PVC-PVDC-PE, Aclar, etc. instead of the permeable PVC films used conventionally. To prevent from light, colored blister films can be used and additionally, individual blister packs should be supplied in duplex cartons. Unfortunately, this is not the practice in many parts of the world. Other better alternate is the use of strip or Alu/Alu packing.

The other solution is the careful selection of ingredients and excipients that are devoid of catalytic impurities or which do not decompose to catalytic products. One simple example here is that of polyethylene glycols, which are routinely used as solvents for drugs in soft gels. The glycols normally contains small amounts of aldehydic impurities and the best way to prevent their interaction with gelatin shell is the use of aldehyde free grade of glycol or heating of commercial grade solvent to expel volatile aldehydic impurities. Similarly, the use of excipients like corn starch can be avoided, till absolutely necessary.

Alternately, specific stabilizers can also be added into the formulations. The protection against aldehydes, whether present initially in the formulation or released in situ, can be provided by the addition of aldehyde scavengers like, lysine, phenylamine, glutamine, hydroxylamine hydrochloride, *p*-amino benzoic acid, glycine, etc.^[49] The in situ release of aldehydes as a consequence to degradation of the contents can be controlled by

the manipulation of pH using buffering agents. Carboxylic acids, such as benzoic acid, fumaric acid, maleic acid, citric acid, etc. are helpful in this direction. The synergistic combination of an amino acid and buffers in preventing pellicle formation has also been explored.^[19] Fig. 13 shows that addition of glycine and citric acid together in the formulation fill proves more effective in preventing dissolution instability than when glycine or citric acid are added alone (Fig. 7).

Some studies have also reported successful prevention of cross-linking using direct inhibitors like semicarbazide hydrochloride, hydroxylamine hydrochloride, piperazine hydrate, pyridine, piperidine, glycerine, *p*-aminobenzoic acid, etc.^[19,49] Another approach, specific to filled hard gelatin capsules, is the addition of disintegrants to the fill powder blend. Capsule formulations containing 10 or more percent of disintegrant is reported to withstand the stress of high humidity storage conditions, presumably due to the porous nature of the capsule fill.^[66] The use of titanium oxide, iron oxide, and color pigments in the capsular dosage forms containing gelatin offers a good protection against cross-linking introduced by light. A good example is that of curcumin, which at a content of 0.4% in the capsule shell, was able to result in a threefold or higher increase in the half-life of the test compounds.^[67] Dyes, like FD&C Yellow No. 5 and Blue No. 1, have also been shown to protect the dosage forms from light.^[18] The synthetic iron oxides, being potent absorbers of wavelengths below 400 nm, can be employed successfully,

except that they have an attached caution that excess iron content (> 15 ppm) can result in discoloration of soft gelatin capsules.^[32]

PATENT STATUS OF STABILIZATION APPROACHES

The use of glycine–citric acid synergistic combination in fills of gelatin capsular products for the purpose of protection against cross-linking is covered by US patent No. 5,674,106^[68] and World patent No. 9733568.^[69] There also exist a few patents where stabilization has been attempted by addition of the stabilizers in the films or gelatin raw material. The incorporation of glutamic acid, tryptophan, or nitrilotrismethylene phosphoric acid or a mixture thereof into gelatin before forming the final product has been claimed to impart improved stability against storage under hot and humid conditions and/or aldehydes.^[70] Addition of a polypeptide content from 15%–70% based on total weight of peptide and gelatin was found to prevent gelatin from becoming insoluble with time without deteriorating the shape retentivity of capsules.^[71]

FUTURE CONSIDERATIONS

Till date, the problem of pelliculization of gelatin products has found major solutions in: 1) understanding of

Fig. 13 The dissolution behavior of triamterene (TRIAM) (a) and hydrochlorothiazide (HCTZ) (b) formulations containing glycine and citric acid (Formula D) on storage at 40°C/85% RH up to 12 weeks. This figure is correlated to Fig. 7 and is from the same reference. The overlapping curves in both cases show that the amino acid/buffer combination is able to neutralize the adverse effect of storage under high humidity and temperature. The figure further depicts that neutralization remains effective even on storing the capsules as long as 12 weeks. (From Ref. [19], p. 498 by courtesy of Marcel Dekker, Inc.)

the chemistry; 2) identification of stabilizers that can be added in formulation fills or films; 3) development of rapid test methods for evaluation of possibility of pellicle formation; and 4) introduction of two-tier dissolution test in USP. Still, a lot has to be done, of which foremost is the adoption of two-tier test by International pharmacopoeias, other than USP. More rigorous efforts need to be done towards stabilization approaches targeted to raw gelatin so that all manufacturers of gelatins around the world are able to offer stable raw material for pharmaceutical use. Concurrently, there is a need for identification of newer types of efficient stabilizers that can be added to the gelatin film during formation of hard and soft gel capsules or in gelatin solutions meant for application as a subcoat in sugar-coated tablets. The hard gel capsule manufacturers produce billions of capsules every year and if solution is offered to them in way of stable gelatin raw material and stabilizers that can be added in the fill/film formula, this can have a very wide impact. The same concept can also be applied at the time of manufacture of soft gels. In case, successes are achieved on this front, the problem is likely to be eliminated to a large extent.

INTRODUCTION

The word “gel” is derived from “gelatin,” and both “gel” and “jelly” can be traced back to the Latin *gelu* for “frost” and *gelare*, meaning “freeze” or “congeal” (1). This origin indicates the essential idea of a liquid setting to a solid-like material that does not flow, but is elastic and retains some liquid characteristics. The distinction between gel and jelly remains somewhat arbitrary, with some differences based on the field of application. The food industry uses the term “gelatin jelly” whereas the pharmaceutical industry uses the term “gelatin gel.”

Use of the term “gel” as a classification originated during the late 1800s as chemists attempted to classify semisolid substances according to their phenomenological characteristics rather than their molecular compositions (2). At that time, analytical methods needed to determine chemical structures were lacking. The USP (3) defines gels (sometimes called jellies) as semisolid systems consisting of either suspensions made up of small inorganic particles, or large organic molecules interpenetrated by a liquid. Where the gel mass consists of a network of small discrete particles, the gel is classified as a two-phase system. Single-phase gels consist of organic macromolecules uniformly distributed throughout a liquid in such a manner that no apparent boundaries exist between the dispersed macromolecules and the liquid.

Single-phase gels and jellies can be described as three-dimensional networks formed by adding macromolecules such as proteins, polysaccharides, and synthetic macromolecules to appropriate liquids. In pharmaceutical applications, water and hydroalcoholic solutions are most common. Many polymer gels exhibit reversibility between the gel state and sol, which is the fluid phase containing the dispersed or dissolved macromolecule. However, formation of some polymer gels is irreversible because their chains are covalently bonded. The three-dimensional networks formed in two-phase gels and jellies are formed by several inorganic colloidal clays. Formation of these inorganic gels is reversible.

Gels are generally considered to be more rigid than jellies because gels contain more covalent crosslinks, a

higher density of physical bonds, or simply less liquid. Gel-forming polymers produce materials that span a range of rigidities, beginning with a sol and increasing in rigidity to a mucilage, jelly, gel, and hydrogel. Table 1 lists monographs for the 23 gel drug products, three jelly drug products, and three nondrug gels listed in the USP.

This review focuses mainly on water-based gels and jellies. Gel structure, the basis for understanding the physical properties associated with gels, is examined first, followed by the rheology of gels. Specific natural, semisynthetic, and synthetic gel-forming polymers and inorganic clays are then discussed along with their pharmaceutical applications.

GEL MICROSTRUCTURE

Substances that form aqueous gels are usually hydrophilic polymers capable of extensive solvation. At certain temperatures and polymer concentrations, and, in some cases, with the addition of ions, a three-dimensional network is formed. Although polymer gels vary considerably in chemical structure, they all behave as elastic solids at low applied stresses, even though they primarily consist of liquid. The differences in chemical composition, however, result in several types of gel microstructure. Pharmaceutical gels may be loosely categorized on the basis of their network microstructure according to the following scheme suggested by Flory (2):

1. Covalently bonded polymer networks with completely disordered structures
2. Physically bonded polymer networks, predominantly disordered but containing ordered loci
3. Well-ordered lamellar structures, including gel mesophases formed by inorganic clays

Covalently Bonded Structures

Covalently crosslinked gel networks are irreversible systems. They are typically prepared from synthetic

Tretinoin Gel	Drug product

hydrophilic polymers in one of two ways, details of which may be found in a comprehensive treatise (4–6). Because the resulting gel matrices are often highly rigid, these gels have been classified as hydrogels.

In the first method of preparation, infinite gel networks arise from the nonlinear copolymerization of two or more monomer species, with one being at least trifunctional. Both the direction and position by which each polymer chain grows during the reaction are random, resulting in the final microstructure of these gels being completely disordered. The gel point for copolymerization between equimolar concentrations of two monomer species can be predicted using the modified Carothers equation (7):

$$\bar{X}_n = \frac{2}{(2 - \rho f_{av})}$$

where \bar{X}_n is the number-average degree of polymerization, ρ is the fractional conversion, and f_{av} is the average functionality of the monomers involved. The gel point is

reached when $X_n \rightarrow \infty$, indicating that the critical conversion for gelation (ρ_c) is equal to $2/f_{av}$ (7). In practice, however, gel points tend to be overestimated by the equation.

The other method for preparing chemically crosslinked gel structures involves covalent crosslinking of individual linear or branched polymer chains, using a low concentration of crosslinking agent (5). The crosslinking ratio X , which is simply the mole ratio of crosslinking agent to polymer repeat units, can be used to characterize the resulting three-dimensional network.

Other parameters to characterize crosslinking are the equilibrium swelling ratio, the molecular weight between crosslinks, the so-called mesh size between crosslinks, and the crosslinking density (8). The equilibrium swelling ratio Q_m is the ratio of the volume of the swollen polymer to the volume of the dry polymer. It decreases as the extent of crosslinking increases. The molecular weight between crosslinks M_c , developed from the Flory equations for

Fig. 1 Chemical and physical crosslinks associated with covalently bonded polymer gels. (a) Bi- and trifunctional chemical crosslinks; (b) simple and trapped physical entanglements; (c) ineffective chemically bonded loop and dangling ends.

equilibrium swelling (9), is also indirectly proportional to crosslinking extent. The mesh size ζ is an estimate of the distance between crosslinks based on the root-mean-square end-to-end distance of the random coil polymer between crosslinks. Estimates of the crosslinking density usually involve more rigorous treatments that require theoretical expressions (6). These models recognize the discrepancy between the amount of crosslinking agent added to the reaction and the number of effective chemical crosslinks actually produced, in addition to the presence of physical crosslinks formed by chain entanglements. If the crosslinking site is known, the covalent crosslinking density may be determined without theoretical models by chemical analysis of these sites (10). Examples of chemical and physical crosslinks, which may exist in a gel network of covalently linked linear chains, are illustrated in Fig. 1.

Physically Bonded Structures

Physically bonded gel networks are reversible systems; factors such as temperature and ion additives can induce a transition between the sol and gel phases. These gels are formed primarily by natural organic polymers (proteins and polysaccharides) and semisynthetic cellulose derivatives. Gels of some synthetic, hydrophilic polymers are also included in this class.

Polymer chains exist most often in the sol as random coils, which undergo conformational transitions to yield a gel (11). Such transitions may involve large ordered sections of one or more chains, which fold into a single, double, or triple helix. The three-dimensional network is then formed by cooperative association of several sections into higher ordered regions called junction zones (12). Many junction zones are dispersed throughout the

amorphous domains of the network, thus giving mechanical strength to the gel.

The microstructures of physically bonded gels are much more complex than those of the disordered, chemically crosslinked gels. The spatial arrangements assumed by polymer chains in forming junction zones may differ, as well as the secondary intermolecular forces that hold these zones together. The physical properties of gels, including rigidity, melting temperature, and yield point, are related to the type of junction zone formed. Several types have been identified or hypothesized; they are briefly reviewed here.

The particular organization of polymer chains in a junction zone depends on the chemical structure of the repeating unit. For example, sulfated polysaccharides (e.g., agar and K-carrageenan) that contain an assortment of sulfated galactose residues form double helices, two or more of which aggregate into multihelical junction zones (12). However, the presence of a few contaminant residue units greatly reduces gelling ability. The residues produce kinks that effectively block helix formation in large sections of chains, indicating that steric fit is critical to gel formation (12). The microstructure of these gels is schematically represented in Fig. 2.

Gels composed of semisynthetic cellulose derivatives, including sodium carboxymethylcellulose, contain microcrystalline junction zones. Residual crystallinity in the form of chain bundles can survive the derivatization processing of cellulose (13). The bundles are connected through common chains to yield a gel, and the ultimate gel strength depends on the efficiency by which the bundles were previously dispersed throughout the sol (13). Furthermore, microcrystalline domains, forming between segments of stereoregular synthetic polymers such as polyvinyl alcohol (14), enhance the gel's rigidity.

Fig. 2 Microstructures associated with physically bonded polymer gels. (a) Multihelical junction zones of agar gels; (b) egg-box model junction zones of calcium alginate gels.

Micelle-like junction zones are formed by methylcellulose and polyethyloxyene polypropyloxyene block copolymers (poloxamers). Although the polymers differ in chemical structure, both have hydrophobic regions in their chains: the di- and trimethyl-D-glucose residues of methylcellulose and the polypropyloxyene block of poloxamer. Another feature common to the two polymers is that their gels exhibit inverted thermal reversibility, that is, they gel with heating and melt with cooling. Both the inverted temperature behavior and the presence of hydrophobic regions in the polymers provide evidence for the formation of micelle-like junction zones (12, 15). Water molecules structured around the hydrophobic regions of polymer chains in a sol become disordered with increases in temperature. Newly exposed hydrophobic regions attract one another to form bonds, whereas hydrophilic areas rearrange to maximize their contact with the aqueous medium. The resulting micelle-like structures continue to grow in size and number at higher temperatures, leading eventually to gel formation.

Other junction zones require the presence of multivalent ions to form ion bridges between polymer chains. An egg box model was proposed by Grant et al. (16) for the formation of calcium alginate gels, in which calcium cations are cooperatively bound between ionized carboxyl

groups located on the polyglucuronate sequences of alginic acid. The cations are coordinated in the interstices of ordered segments of the polysaccharide chains (Fig. 2b). Other mechanisms for the involvement of ions in gelation may be similar but less precisely understood. For instance, guar gum forms cohesive gels only in the presence of borate ions (17).

Finally, some physically bonded gel networks are held together by simple entanglement couplings between individual polymer chains rather than by large aggregate junction zones. Above a critical concentration, long chains of hydrophilic polymers, such as hyaluronic acid and carbomer, are apparently forced through the domains of other chains because of their large molecular volumes (18). An increasingly intertwined network occurs with higher polymer concentrations to produce a gel. Although these gels are highly disordered compared with other physically bonded gels that have ordered junction zones, they are considered here because they form reversible gel microstructures. Yet, some researchers believe (12) that ordered regions must be present to impart rigidity in entangled gels, but such regions may be relatively dispersed and unstable, making them difficult to identify. Others propose (19) that higher order exists from interchain bridging by complexation with solvent molecules.

Molecular associations between polymer segments occur through the cooperation of several intermolecular forces such as hydrogen bonding, van der Waals forces, and electrostatic attractive and repulsive forces. The disruption of junction zones is associated with a high activation energy, further indicating that many intermolecular forces cooperate to retain the structure of each junction (12).

Well-Ordered Gel Structures

Under suitable conditions, certain silica, alumina, and clay aqueous dispersions form rigid gels or lyogels. When clays belonging to the smectite class, such as bentonite, aluminum magnesium silicate, hectorite, and laponite, come into contact with water, they undergo interlayer swelling spontaneously, followed by osmotic swelling to produce a gel (20). The plate-like clay particles associate into an ordered, extended network for which two models have been described (21). The “house of cards” model is based on attraction between weak positively charged particle edges and negatively charged particle faces; edge-to-edge associations of particles into flat ribbons have also been proposed.

Highly ordered lamellar gel microstructures are formed by certain surfactants and mixtures of a surfactant and long-chain fatty alcohols in water. Using small angle X-ray scattering (SAXS), an ordered lamellar stack lattice model was proposed for the gel formed by 10% w/w cetostearyl alcohol containing 0.5% cetrimide surfactant (22). In contrast, the microstructure of a Brij 96 gel depends on the surfactants concentration. A hexagonal liquid-crystalline gel structure was detected by SAXS at concentrations of 40 to 60 wt% in water, whereas an extended lamellar structure was detected at higher concentrations (70 to 85 wt%) (23).

PHYSICAL PROPERTIES OF GELS AND JELLIES

The physical properties of gels and jellies can be classified into two groups: transitional properties (including gel point, retrogradation, and syneresis) and rheological properties (including rigidity, yield point, and rupture strength). The experimental techniques used to characterize these physical properties can be similarly classified (24). Spectrophotometric and thermal techniques are used to identify gel microstructures (physical junction zones) and their related transitional properties. For example, nuclear magnetic resonance (NMR) spectroscopy

measures the structural and dynamic characteristics of the polymer just prior to aggregation and gel formation, and circular dichroism (CD) spectroscopy measures the conformational changes of the polymer during network formation (e.g., helix–coil transitions). Mechanical techniques are used to determine rheological properties of gels. These techniques employ either small-deformation measurements that yield viscoelastic parameters or large-deformation measurements that generate complete stress-strain profiles, which include failure parameters.

Transitional Properties

Sol–gel transition (gel point)

Sol–gel transition may be dependent on polymer concentration or temperature. Spectrophotometric methods, as mentioned previously, are used to probe sol–gel transitions that depend on the critical gelling concentration. Thermal methods, including differential scanning calorimetry, are used to measure sol–gel transitions, or melting temperatures, of thermoreversible gels. A relationship for estimating the heat of gelation was derived by Eldrige and Ferry (25) in which the dependence of the sol–gel transition temperature on polymer concentration was considered.

The critical gelling concentration is the concentration below which no macroscopic gel is formed under the prevailing experimental conditions (24); rather, a sol is formed by the polymer and solvent. This concentration depends on polymer–polymer and polymer–solvent interactions, the hydrophilic–lipophilic character of the polymer, and the molecular weight and flexibility of the chain (26). Furthermore, polymers that require ions to form gels have critical gelling concentrations that depend on the concentration of these additives and many other variables. Table 2 lists ranges of minimal concentrations for substances to gel in water.

There are two thermal gel points associated with thermoreversible gels. Shifts in temperature may cause gel formation at the setting point or gel liquification at the melting point. In addition, temperature hysteresis may occur in some gels in which the gel-setting point is lower than the melting point. The hysteresis behavior indicates that junction zones constitute a family of associations rather than a set of identical crosslinkages (12). Agarose gels show temperature hysteresis; the gel sets at about 40°C and melts at about 90°C.

Physical aging

Most gels have structures that have not attained equilibrium; different preparative methods and conditions

Table 2 Gelling concentrations for substances used in pharmaceutical products

Substance	Gel-forming concentrations (wt %)	Required additives
Proteins		
Collagen	0.2–0.4 ^a	
Gelatin	2–15	
Polysaccharides		
Agar	0.1–1	
Alginates	0.5–1	Ca ²⁺
	5–10	Na ⁺
K-Carrageenan	1–2	K ⁺
Gellum gum (low acetyl)	0.5–1	Ca ²⁺
Glycyrrhiza	2	
Guar gum	2.5–10	
	0.25	Borate ion
Hyaluronic acid	2	
Pectins (low methoxy)	0.8–2	Ca ²⁺
Starch	6	
Tragacanth gum	2–5	
Semisynthetic polymers (cellulose derivatives)		
Carboxymethylcellulose	4–6	Na ⁺
	10–25	Na ⁺
Hydroxypropylcellulose	8–10	
Hydroxypropylmethylcellulose	2–10	
Methylcellulose	2–4	
Synthetic polymers		
Carbomer	0.5–2	
Poloxamer	15–50	
Poyacrylamide	4	
Polyvinyl alcohol	10–20	
Inorganic substances		
Aluminum hydroxide	3–5	
Bentonite	5	
Laponite	2	Electrolytes
Surfactants		
Cetostearyl alcohol	10	Cetrimide
Brij 96 ^b	40–60	

^a Adjusted to pH > 4 and warmed to 37°C.^b Brij 30–99 surfactants are polyoxyethylene-alkyl ethers.

influence the gel state. The gel physically ages as it moves toward equilibrium, making the history of a gel sample an important consideration when measuring physical properties. Aging reflects changes in gel microstructure, where noncovalent crosslinks are breaking and reforming. Furthermore, instabilities caused by the nonequilibrium state arise in some polymer gels; two examples are retrogradation and syneresis.

Retrogradation is the spontaneous reversion of a polymer solution to a gel on standing. Polyvinyl alcohol dissolved in water undergoes retrogradation, whereby the stereoregular chains form microcrystalline aggregates as

the solution ages (14). Polyvinyl alcohol gels also retrograde, forming crystalline domains. Amylase, which is the linear polysaccharide fraction of starch, undergoes retrogradation, reducing the physical stability of starch solutions and gels over time.

Syneresis is the process whereby liquid is liberated spontaneously from the gel matrix. This instability arises from the nonequilibrium state of the gel established as it sets or because of a change in external conditions. At equilibrium, elastic contraction forces of polymer chains are usually balanced by solvent swelling forces, resulting from an osmotic pressure differential (27). With changes in

temperature, for example, the osmotic pressure shifts, causing an elastic contraction of polymer chains. The contractive response squeezes excess liquid out of the matrix. Agar and carrageenan are examples of gels that exhibit syneresis.

Rheological Properties

Like the transitional physical properties, the rheological properties of gels are not easily characterized because they depend strongly on the attributes of the polymer, history of the gel sample, and experimental conditions. Most often, the apparent viscosity or gel strength increases with an increase in the effective crosslink density of the gel or in the concentration and average molecular weight of the polymer. However, a rise in temperature may increase or decrease the apparent viscosity, depending on the molecular interactions between the polymer and solvent. In addition, the direction of change in apparent viscosity may not be readily predictable when additives such as ions, nonelectrolytes, solvents or nonsolvents, and other compatible polymers are mixed with a gel.

Viscoelasticity

Under an applied stress, which is the force per unit area, ideal liquids flow and perfectly elastic solids deform. The rate of shear, $d\gamma/dt$, is the measure of liquid deformation (flow): viscosity η is a liquid's resistance to flow, strain γ is the measure of solid deformation, and the shear modulus G is the resistance to strain for stresses applied tangentially to the solid's surface. Clearly, gels are semisolids that have both solid and liquid character under stress—they are viscoelastic substances.

Depending on their rheological properties, physically bonded gels can be divided into three groups: entanglement networks, strong gels, and weak gels (24). Entanglement networks behave as dilute solutions when diluted below their critical gelling concentrations, whereas strong gels have stress-strain profiles that include rupture points. Examples of polymers that form entanglement networks are guar gum and hyaluronic acid; strong gels are formed by agar, calcium alginate, gelatin, and pectin.

Weak gels are also entanglement networks, but they undergo specific molecular interactions that increase their strength (24). Therefore, the rheological properties of weak gels are intermediate between those of entanglement networks and strong gels. Xanthan gum and carbomer are examples of polymers that form weak gels. Hyaluronic acid generally forms an entanglement network, but under specific conditions (pH 2.5 and 0.15 *M* salt), it forms a weak gel (28).

Types of flow

The flow associated with entanglement networks and weak gels can be readily measured with continuous-shear instruments, such as the Ferranti-Shirley cone and-plate viscometer. These instruments characterize the gel behavior over a range of shear rates; a complete rheogram is usually generated for a particular gel in order to identify its flow behavior. If the shear stress versus shear rate curve is concave toward the shear-rate axis, the gel exhibits pseudoplastic flow. The internal gel microstructure breaks down with increases in shear rate, which lowers the apparent viscosity (it "shear-thins" the gel). However, if a gel does not flow at low stresses, but only above a finite stress, it exhibits plastic flow. The yield point, which is a measure of gel strength, is the stress at which flow begins. In general, entanglement networks and weak gels exhibit pseudoplastic and plastic flow, respectively.

Entanglement networks and weak gels may exhibit thixotropy, or time-dependent flow, in addition to exhibiting either pseudoplastic or plastic flow. Thixotropy, which is noted in a rheogram as a hysteresis loop, occurs because the gel requires a finite time to rebuild its original structure that breaks down during continuous shear measurements. The degree of thixotropy depends on gel type, sample history, and experimental conditions.

Dynamic oscillatory techniques use small-deformation measurements to determine the viscoelastic properties of gels within the linear region. Unlike continuous shear instruments, oscillatory instruments (e.g., the Weissenberg rheogoniometer) have the advantage of not altering the gel microstructure because small deformations are made with a sinusoidally oscillating stress or strain. For an ideal elastic solid, the stress and strain are in phase, whereas for an ideal liquid, the stress and strain have a phase difference of 90°. Viscoelastic materials, including gels, have phase angles between 0 and 90°. The parameters obtained through oscillatory testing are the storage modulus G' which reflects solid-like properties, and the loss modulus G'' , which reflects liquid-like properties. These moduli depend on the frequency of oscillation.

Details of both continuous shear and dynamic oscillatory testing of pharmaceutical semisolids, including gels, have been addressed in reviews (29, 30), where the fundamental viscoelastic principles are further developed along with a discussion of data analyses and interpretations.

Rigidity

The modulus of rigidity, or shear modulus (G), is defined as the ratio of shear stress to strain. It is a measure of a gel's ability to resist deformation. The minimum rigidity for a strong gel to resist deformation under its own weight is

equal to about $g\rho l$ which is the product of the acceleration due to gravity (g), density (ρ), and a linear dimension (l) of the sample. Therefore, the minimum rigidity is about 100 Pa (10^3 dyn/cm) for a gel sample 1 cm long.

An empirical measure of gel rigidity is the measurement of gelatin gel strength, also known as Bloom strength. The procedure is described in the USP (31). It is the determination in a Bloom gelometer of the gram weight needed to depress a standardized plunger 4 mm into the surface of a 6.67% (w/w) gel after maturing the gel at 10°C for 17 h. The Bloom gelometer, however, has largely been replaced by the Stevens LFRA/Voland Texture Analyzer and the TA.XT2 Texture Analyzer (Micro Systems).

Rupture strength

Rupture strength is equal to the stress at which a strong gel ruptures or fails rather than undergoing further strain. The rupture strength is determined by large-deformation measurements on instruments such as the Instron tester, where a tensile stress is applied to the sample. However, strong gel samples can only be tested in tension if they can support their own weight (24), and most physically crosslinked gels are relatively weak, making this type of test difficult.

GEL-FORMING SUBSTANCES AND THEIR PHARMACEUTICAL USES

Gel-forming hydrophilic polymers are typically used to prepare lipid-free semisolid dosage forms, including dental, dermatological, nasal, ophthalmic, rectal, and vaginal gels and jellies. Gel vehicles containing therapeutic agents are especially useful for application to mucous membranes and ulcerated or burned tissues because their high water content reduces irritancy. Furthermore, these hydrophilic gels are easily removed by gentle rinsing or natural flushing with body fluids, reducing the propensity for mechanical abrasion. The superior optical clarity of synthetic polymer gels, such as those composed of poloxamer and carbomer, has led to the current interest in developing therapeutic ophthalmic gels.

Unconventional routes of drug administration by using gels and jellies are also being explored. Thus, two nasal jellies were developed and marketed. The intranasal vitamin B-12 gel, Nascobal (Schwarz Pharma), is used as a dietary supplement. The gel base is composed of a hydrophilic cellulose derivative, the exact nature of which is not disclosed. However, the gel is apparently odorless and nonirritating, and adheres well to the mucous

membrane. Neo-Synephrine Viscous (Sanofi Winthrop) is a water-soluble nasal jelly formulated with methylcellulose; it contains the decongestant phenylephrine hydrochloride.

In addition to serving as drug-containing vehicles, some gels have other important functions. For example, a soft, flexible gel applied to burned skin can prevent excessive water loss by forming a physical barrier. Ocular gel inserts are designed to lubricate the eye continuously and promote healing. Still other gels are intended for lubricating surgical and medical instruments in order to minimize local irritation.

Many gel-forming substances are available for preparing pharmaceutical gels and jellies. Although these substances share some common physical characteristics, the intended use may require gelling attributes of a certain substance or blend of substances. Table 3 lists the favorable properties of pharmaceutical gels for particular applications.

Proteins

Collagen

Collagen is the major connective tissue protein in animals. The collagen molecule is considered to be a block copolymer, formed with blocks of glycine (33%) and proline and hydroxyproline (23%), between blocks of the remaining amino acids (44%). Tropocollagen is the asymmetrical subunit of collagen, which is made up of three peptide chains wound in a triple helix. The nonhelical portions of collagen, so-called telopeptides, are susceptible to enzyme digestion. Native collagen is insoluble in water, but 2% to 3% may be solubilized in dilute acidic solutions. Collagen may also be solubilized by treatment with proteolytic enzymes, which digest the telopeptide portions (e.g., Vitrogen, Collagen Corp.).

The asymmetrical molecular structure of collagen permits the formation of rigid gels; highly rigid structures are obtained at 0.1% concentration by UV irradiation or chemical crosslinking with aldehydes (32). These gels are used as biomaterials for vitreous replacements. Pepsin-solubilized collagen forms clear, rigid gels; they are prepared with a 0.2% to 0.4% collagen solution, which consists of unassociated molecules and small fibrils when cooled to $\sim 5^\circ\text{C}$. As the temperature is raised to 37°C , the collagen molecules aggregate, forming subfibrils that further aggregate to form the gel network (33). The rigidity is then increased by lightly crosslinking with aldehydes.

Optically clear collagen gels have been considered for use in ophthalmic drug delivery. Ocular inserts of succinylated or methylated collagen are patented as soluble

Table 3 Pharmaceutical gels

Applications	Favorable properties
Dental	Highly thixotropic Optimal viscosity for filling fissures Adherent to enamel surfaces Optically clear Water soluble Orally digestible
Dermatological	Thixotropic Good spreadability Greaseless (especially for acne preparations) Easily removed Emollient Demulcent (especially for abraded tissue) Nonstaining Compatible with a number of excipients Water soluble <i>or</i> miscible
Nasal	Adherent Odorless Nonirritating Water soluble
Ophthalmic	Optically clear Sterile Mucomimetic Lubricating Demulcent Nonirritating or nonsensitizing Water soluble or miscible
Surgical and medical procedures	Lubricating Adherent to instrument surfaces Maximal contact with mucous membranes Nonirritating
Vaginal	Acid stable Adherent Does not liquify at body temperature Slow dissolving Lubricating Greaseless and nontacky Nonirritating

devices for drug delivery (34). Constant, controlled release of pilocarpine hydrochloride was maintained for 5 to 15 days with crosslinked collagen and other collagen-derivative inserts (35). A corneal shield made of non-crosslinked collagen is marketed as Bio-Cor by Bausch & Lomb. This shield is placed over an eye injury and, as collagen slowly dissolves, the cornea is continuously lubricated to promote healing. Collagen implants (Lacrimedics) are also used for relief of dry eye by partially blocking tear removing canals; the implants dissolve within 7 to 10 days. Collagen gels are also used in hemostasis. A lightly crosslinked sterile pad, Instat hemostat (Johnson &

Johnson), assists in forming blood clots to arrest bleeding during surgery.

Gelatin

Gelatin is denatured collagen, which is hydrolytically degraded under acid or alkaline conditions to produce Type A or B gelatins, respectively. The amino acid content of acid-processed gelatin is virtually identical to that of collagen, yielding an isoelectric point, *pI*, between 8 and 9. In contrast, alkaline processing reduces the ratio of amide groups to carboxyl groups, thereby shifting the *pI* to about 4 or 5.

Gelatin forms elastic gels reversibly by cooling solutions that contain a sufficient concentration. The gel microstructure consists of a three-dimensional network held together by junction zones in which gelatin chains have partly refolded into the triple helix of the parent collagen molecule (36). The physical properties associated with gelatin gels depend on protein concentration, average molecular weight, temperature, pH, and additives (37).

The swelling kinetics of uncrosslinked type B gelatin films in the absence (38) and presence of additives (39) was studied. The water-swelling kinetics of chemically crosslinked matrices (40) were considered for controlling the release of therapeutic agents. Heat-crosslinked gelatin matrices were also examined for drug release (41). Both, the molecular weight between crosslinks, M_c , and the mesh size between crosslinks, ζ , were used to characterize gelatin gel matrices (42) during release of the macromolecular solute dextran. The crosslinking extent and density in gelatin matrices was directly determined by chemical analysis of the uncrosslinked primary amino groups and compared with swelling parameters of crosslinking (10).

Although gelatin has been used by the pharmaceutical industry for mainly producing soft and hard gelatin capsules, some commercial products use a hydrated gel form. The sterile product, H.P. Acthar Gel (Rorer), contains 16% gelatin for sustaining the release of adrenocorticotrophic hormone from an intramuscular or subcutaneous injection. A sterile, absorbable gelatin sponge, Gelfoam (UpJohn), which has a lightly crosslinked matrix, is used during surgery to absorb blood and promote clotting. An absorbable gelatin film, Gelfilm Ophthalmic (Upjohn), is available for use in ocular surgery. The ocular implant requires 2 to 5 months for complete absorption.

Polysaccharides

Alginates

Alginic acid is processed from brown seaweed, using a dilute acid, followed by alkalization with soda ash to yield the water-soluble salt form, sodium alginate. Alginic acid is a linear glycuronoalcan composed of polymannuronic acid blocks (M), polygluconic acid blocks (G), and mixed blocks of these two uronic acids (MG) (43). The gelling properties and gel microstructure of the various salt forms of alginic acid depend on the M, G, and MG block content. High-M alginates form turbid, weak gels, and high-G alginates form transparent, brittle gels. Gelation depends on the cation type; sodium alginate gels are water-soluble, whereas calcium alginate gels are insoluble, yet swell in water. Many "egg box" junction zones are formed

by calcium cations and G blocks to create such rigid gel networks.

Sodium and calcium alginate are used in commercial pharmaceutical formulations. Sodium alginate gels have superior spreading and lubricating properties; they are also nontacky and tasteless, and have emollient qualities. Moreover, sodium alginate is compatible with many compounds such as starch, sodium carboxymethylcellulose, pectin, carrageenan, 25% ethanol, 4% sodium chloride, and most alkali salts (44). Taking advantage of this compatibility and the favorable gel properties, sodium alginate is formulated with sodium carboxymethyl cellulose in the nonirritating, water-soluble lubricating jelly, Ortho Personal Lubricant (Ortho). Calcium alginate is used as a wound dressing for varicose and decubitus ulcers (45), where it forms a hydrophilic gel over the wound by absorbing exudate, which promotes healing. The high rigidities of calcium alginate gels make them suitable for preparing dental impressions and as matrix barriers for controlling drug delivery (46). Theophylline release was studied from granules coated with sodium alginate and calcium lactate through insoluble gel formation (47).

Carrageenan

Carrageenan, a sulfated polysaccharide extracted from red seaweed, may be separated into a number of fractions depending on the species, season, and environment. The three major fractions, lambda-, iota-, and kappa (κ)-carrageenan, contain an alternating sequence of (1 \rightarrow 4)-linked (β -D-galactopyranosyl and (1 \rightarrow 3)-linked α -D-galactopyranosyl residues, but they differ in the degree and sites of sulfation (48). Of these three fractions, only lambda-carrageenan cannot form gels.

Under optimal ionic strength and polymer concentration, κ -carrageenan forms rigid, thermoreversible gels in the presence of cations. The elastic moduli of these gels depend on the type of cation and follow the Hofmeister series: $\text{Cs}^+ > \text{Rb}^+ > \text{K}^+ \gg \text{Na}^+ > \text{Li}^+$. The κ -carrageenan gel also undergoes syneresis, the spontaneous liberation of liquid from the matrix. Early models for gelation envisioned multihelical junction zones composed of polysaccharide chains folded into double helices. This model was extended to accommodate cations in that the formation of the helical domains would require mediation by the cations themselves (49). However, other researchers propose (50) an indirect role for cations in which they alter solvent structure around the κ -carrageenan helices, thereby inducing gel formation. Differential scanning calorimetry and isothermal titration calorimetry were used to study mono- and divalent cation binding and induced conformation changes in κ -carrageenan (51).

Gels made with κ -carrageenan and potassium ions have excellent lubricity and emollient properties. Because of such favorable gelling characteristics, these gels are used as vehicles for the topical administration of drugs and as gelling agents in other pharmaceutical preparations. They can also be used in combination with sodium carboxymethylcellulose, which interferes with gel formation resulting in a variety of consistencies and textures. Theophylline and diclofenac sodium release were studied from tablet matrices containing κ -carrageenan and iota-carrageenan with KCl or CaCl_2 (52).

Hyaluronic acid

Hyaluronic acid is a linear glycosaminoglycan (an aminopolysaccharide), which is an important component of synovial fluid and the cellular matrix of connective tissue. It comprises a biological gel that supports cells, maintains tissue hydration, and functions as a lubricant and shock absorbent in joints (53). Hyaluronic acid forms transparent, rigid gels at 2% concentration, although they are not as rigid as agar and carrageenan gels. The gel microstructure is constructed by entanglement couplings among the long polysaccharide chains, which have molecular weights ranging from about 1×10^6 to 4×10^6 Da, depending on the source of animal tissue.

A 1% viscoelastic jelly of the sodium salt is commercially available as Healon (Kabi Pharmacia), which is widely employed in ophthalmic surgery. Sodium hyaluronate jelly provides a nonirritating viscoelastic medium for separating tissues during surgery and prevents postoperative adhesion formation (53). Investigators in a clinical trial of intraarticular injections of 500–730 kDa sodium hyaluronate (Hyalgan, Sanofi) for osteoarthritis concluded that this treatment might delay the structural progression of the disease (54). When hyaluronic acid was tested as an ophthalmic gel (55), its mucoadhesive properties improved the ocular bioavailability of tropicamide.

Pectins

Pectins are a complex group of polysaccharides, the structures of which vary with plant source. They are heteropolysaccharides that are extracted from apple pomace and citrus fruit rinds and consist mainly of polygalacturonic acids. The degree of esterification determines the gelation process and, hence, the eventual commercial use. High-methoxy (HM) pectin gels in the presence of high concentrations of sucrose at acidic pH. The sucrose dehydrates pectin to a gel. High-methoxy pectins are used in sweet food products such as fruit jams and preserves.

In contrast, low-methoxy (LM) pectins gel in the presence of divalent cations, especially calcium, by the “egg box” mechanism proposed for alginates. Moreover, calcium pectinate gels prepared at neutral pH are heat stable, whereas acidic pH gels are thermoreversible (56). Gel strength depends on the extent of esterification (levels from 30% to 50% are optimal), the distribution of ester groups on the chain, and the average molecular weight. LM pectins have been used traditionally in antidiarrheal formulations with kaolin. HM pectins were evaluated in controlled release matrix formulations (57). Pectin microspheres were reported to improve ophthalmic bioavailability of piroxicam in rabbits compared with commercial piroxicam eye drops (58).

Starch

Starch is the principal polysaccharide of higher plants and can be extracted from a number of sources, including corn, wheat, and potato. Starch granules can be fractionated into two structurally distinct polysaccharides: 30% amylose (linear polymer) and 80% amylopectin (branched polymer). Starch is insoluble in cold water because of extensive hydrogen bonding between polysaccharide chains. However, the hydrogen bonds break at temperatures above the gelatinization range of 60°C to 70°C, allowing the granules to swell. The starch sol can then form a gel on cooling. The type of gel depends on the starch species; corn starch forms opaque, rigid gels, whereas potato starch forms clear, nonrigid gels (59).

The microstructure of starch gels is an example of a matrix strengthened by filler. Heating causes the amylopectin granules to become swollen and porous, whereas the linear amylose chains dissolve. As the solution cools, amylose sets into a gel matrix that threads through the porous amylopectin granules, thereby producing a reinforced gel (60).

Aqueous starch solutions exhibit retrogradation in which crystalline aggregates form spontaneously over time with Brownian movement. As the solution ages, it becomes opalescent, followed by the gradual precipitation of starch. Starch gels are also unstable because of the formation of crystalline aggregates; however, they undergo syneresis. The amylose fraction is responsible for these instabilities; amylose chains are linear, enabling them to become parallel in order to form aggregates. Starch has been used extensively as a pharmaceutical excipient in tablets, serving as a filler, binder, and disintegrant. Starch gels have found limited use as skin emollients. Starch has been examined as a mucoadhesive in microparticles to improve protein uptake across the nasal mucosa (61).

Table 4 Miscellaneous polysaccharide gelling agents and their uses

Agent	Notes	Product or experimental use	Ref.
Agar	Soluble at $> 90^{\circ}\text{C}$	Molecular structure	(62)
	Rigid gel from $\sim 0.1\%$	Bulk laxative	(63)
	Multihelical junction zones	Rectal administration of insulin	(64)
		Suppository base with NaCMC	(65)
Gellan gum	Good optical clarity	Timoptic-XE (Gelrite; Merck)	
	Forms gels with cations	In situ gelling polymer for ophthalmic delivery	(66)
Glycyrrhiza	Gels are pseudoplastic and thixotropic	Enhanced colon calcitonin absorption	(67)
	Efficient bitter taste masker	Vehicle for antiviral idoxuridine	(68)
Guar gum	Liquifaction at $< \text{pH } 7$		(69)
	Nonionic	Sustained release of quinidine sulfate	(70)
	Binds free water to eliminate syneresis	Colon specific drug carrier	(71)
Tragacanth gum	Acid stable ($\text{pH} \sim 2$)		(72)
	Restore vaginal acidity	Aci-Jel (Ortho)	
	Gel vehicle	Ephedrine sulfate jelly, USP	

Miscellaneous carbohydrates

Table 4 lists less frequently used agents and a few notes about their properties. Also listed are products or experimental uses and references.

Semisynthetic Polymers (Cellulose Derivatives)

Carboxymethylcellulose, sodium

Sodium carboxymethylcellulose (NaCMC) is a carboxymethyl ether of cellulose, the ubiquitous polysaccharide composing the fibrous tissue of plants. The hydroxyl groups on the 2-glucopyranose residues of cellulose are replaced by carboxymethyl groups; the number of replacements is known as the degree of substitution DS. Both the DS and polymer chain length determine the solubility, viscosity, and gel strength of NaCMC. It dissolves in water and mixtures of water with the lower alcohols and glycerin. Aqueous gels are stable from pH 2 to 10 but susceptible to microbial growth.

The microstructure of NaCMC gels was examined on freeze-fractured samples with a transmission electron microscope (73). A fine, quasi-crystalline structure consisting of filaments with thicknesses of 2 to 3 nm was identified. These filaments are microaggregates of individual polymer chains. The rigidity of NaCMC gels can be increased by adding multivalent cations such as Al^{3+} or Fe^{2+} , resulting in ionic bridges between the cations and ionized carboxyl groups (74). These gels are stable indefinitely.

Because of its acid stability, NaCMC is suitable for therapeutic vaginal gels. The base of Ortho-Gynol contraceptive jelly (Ortho) is formulated with NaCMC, water, and propylene glycol and adjusted to pH 4.5 with acetic acid. NaCMC also composes the gel base of Glucose (Paddock), which contains 40% dextrose and is used to treat hypoglycemia. In a study of NaCMC gels as the vehicle for a recombinant human platelet-derived growth factor for treatment of non healing diabetic ulcers, the gel vehicle alone was reported to have a higher healing rate compared to good wound care alone (75).

Hydroxypropyl cellulose

Hydroxypropyl cellulose is produced by substituting propylene oxide for hydroxyl groups on alkalinized cellulose. This cellulosic derivative is soluble in cold water and many polar organic solvents such as methanol, ethanol, isopropanol, and propylene glycol (76). The alcohol solubility increases with increasing degrees of hydroxypropyl substitution. Aqueous preparations of hydroxypropyl cellulose are susceptible to hydrolysis (acid unstable); therefore, a pH of 6 to 8 provides optimum stability. Photodegradation and limited biological degradation may also occur.

Hydroxypropyl cellulose gels on heating and forms thermoreversible gels. The pharmaceutical gel products containing hydroxypropyl cellulose take advantage of its compatibility with alcohol. The microviscosity of hydroxypropyl cellulose gels was evaluated for prediction of drug diffusion rates (77). Examples of commercial products with alcoholic and hydroalcoholic gel bases are given in Table 5.

Table 5 Pharmaceutical gel products containing hydroxypropyl cellulose or hydroxypropyl methylcellulose

Brand name	Manufacturer	Therapeutic agent; activity	Alcohol content (%)
Hydroxypropyl cellulose			
Compound W Gel	Whitehall	Salicylic acid; keratolytic	67.5
DuoPlant Gel	Schering-Plough	Salicylic acid; keratolytic	57.6
Erygel	Herbert	Erythromycin; antibiotic for acne	92
Hydrisalic Gel	Pedinol	Salicylic acid; keratolytic	100
Keralyt Gel	Summers	Salicylic acid; keratolytic	19.4
Lacrisert Insert	Merck & Co.	Hydroxypropyl cellulose; lubricant	0
Retin-A Gel	Ortho	Retinoic acid; antiacne	90
Hydroxypropyl methylcellulose			
ArthriCare Triple-Medicated Gel	Commerce	Methyl salicylate; menthol, methyl nicotinate; liniment	
Persa-Gel W	Ortho Derm	Benzoyl peroxide; antibacterial	
Xylocaine Jelly	Astra	Lidocaine HCl; anesthetic	

Hydroxypropyl methylcellulose

Hydroxypropyl methylcellulose (HPMC) is produced similarly to hydroxypropyl cellulose except that methyl chloride is included in the reaction. The composition of the substituted hydroxyl groups ranges from 3% to 12% hydroxypropyl and from 19% to 30% methyl. HPMC is soluble in cold water and the polyethylene glycols up to 600 Da, but, in contrast to hydroxypropyl cellulose, HPMC is not soluble in alcohol. It is also less susceptible to hydrolysis, and is stable from pH 3 to 11.

Aqueous gels are formed on heating; the gel point ranges from 50°C to 90°C, depending on the grade (78). Addition of small amounts of water-miscible solvent, such as ethanol and the glycols, raises the gel point. Examples of HPMC-based pharmaceutical gels that contain only water are included in Table 3. The good lubricating and adherent qualities of HPMC gels are exploited in Xylocaine 2% Jelly (Astra), which is used to minimize discomfort associated with medical procedures. A 2% solution (80 kDa) is commercially available as an ophthalmic surgical aid (OcuCoat; Storz). The influence of indomethacin, propranolol HCl, and tetracycline HCl was studied on the properties and swelling characteristics of matrix gels containing hydroxypropyl methylcellulose and methylcellulose (79).

Methylcellulose

Methylcellulose is a cellulose ether in which methyl groups have been substituted for hydroxyl groups on the 2-glucopyranose residues. It is soluble in cold water at low methoxy contents; increased substitution increases the solubility in hydroalcoholic and alcoholic solutions (80).

Aqueous solutions of methylcellulose gel on heating, whereby micelle-like junction zones form throughout the network. Gel strength and gelling temperature depend on the concentration, degrees of substitution, and average molecular weight. The gelling temperature can be lowered by adding sugar or most electrolytes, which reduce polymer hydration.

High viscosity grades of methylcellulose are used in pharmaceutical gels. The gels are demulcent and have good surfactant properties, which permit easy spreading on body tissues. Therefore, methylcellulose gels are used as dressings for burned tissue because they minimize water loss and are easily removed. The high viscosity grades are used in ophthalmic preparations such as Murocel artificial tears (Bausch & Lomb) and Neo-Synephrine viscous solution (Sanofi Winthrop). Other pharmaceutical applications include the bulk-forming laxative, Citrucel (SK-Beecham), and lubricating jellies for surgical and medical procedures. A methylcellulose gel was investigated for topical administration of tetracycline HCl (81). The bioadhesive properties of 3% methylcellulose gels on slowing mucociliary clearance were examined using a rate model (82).

Synthetic Polymers

Carbomer

Carbomer is a synthetic polyacrylic acid resin, which is copolymerized with about 0.75 to 2% polyalkylsucrose (83). This is the reason why aqueous dispersions of carbomer must be protected against microbial growth. Carbomer is a high molecular weight polymer that contains carboxylic acid groups on about two thirds of its

repeat units. Gels are formed on neutralization between pH 5 and 10 with metal hydroxides or amines such as diisopropanolamine and triethanolamine. Neutralization expands the long chains of carbomer by charge repulsion to produce an entangled gel network. Because electrostatic repulsion plays a critical role in forming a gel, viscosity and gel strength depend on both pH and salt content.

The molecular size of carbomer is important in determining gel properties and applications. Carbomer 934 and 940, with average molecular weights of 3×10^6 and 4×10^6 Da, respectively, are most commonly used by the pharmaceutical industry. Both grades have favorable rheological properties for topical applications; the gels undergo plastic flow (84) and have temperature-stable viscosities (85). The gels can be formulated with large quantities of alcohol, but the alcohol dehydrates the polymer network and lowers the viscosity. Ostrenga et al. conducted a systematic investigation of propylene glycol/water vehicles gelled with 1% carbomer to optimize percutaneous absorption of fluocinolone acetonide and fluocinonide (86). These investigators showed under specified conditions that an increasing partition coefficient of the steroid between the vehicle and isopropyl myristate increased the uptake of drug into the skin. These studies laid the ground for commercial use of such gels for a range of steroids.

Carbomer is also compatible with dimethyl sulfoxide. The veterinary product, Domoso (Syntex Veterinary Labs), is a topical gel consisting of carbomer 934 and 90% dimethyl sulfoxide. Carbomer 940 gels exhibit superior optical clarity compared with 934 gels (87), and can be used in ophthalmic preparations. However, only carbomer 934 is approved for internal use. The mucoadhesive properties of carbomer were studied with triamcinolone acetonide (88), with acyclovir (89, 90) and to improve protein uptake across the nasal mucosa (61). Pharmaceutical gel products containing carbomer in their formulations are listed in Table 6. All are dermatological gels except for Anbesol Gel (Whitehall) and Pilopine HS (Alcon).

Poloxamer

Poloxamer is the generic name for a series of block copolymers that are composed of one polypropylene oxide block sandwiched between polyethylene oxide blocks. For example, poloxamer 188 can be written as (PEO)₇₅-(PPO)₃₀-(PEO)₇₅. The poloxamers serve as high molecular weight surfactants because the PEO blocks are hydrophilic, whereas the PPO blocks are hydrophobic.

At relatively high concentrations (>20%), poloxamers form thermoreversible gels; however, they gel on heating rather than cooling. The amphiphilic nature supports the

Table 6 Pharmaceutical gel products containing carbomer

Brand name	Manufacturer	Therapeutic agent; activity
Carbomer 934		
Anbesol Gel	Whitehall	Benzocaine, anesthetic; antiseptic
Cleocin T Gel	Upjohn	Clindamycin; antibiotic for acne
Persa-Gel W	Ortho	Benzoyl peroxide; antibacterial
Therapeutic Mineral Ice Gel	Bristol-Meyers	Menthol; liniment
Ben-Gay Vanishing Scent Gel	Pfizer	Menthol, camphor; liniment
Sportsman Ice Gel	Thompson	Menthol; liniment
Carbomer 940		
Benzac W	Galderma	Benzoyl peroxide; antibacterial
Benzagel	Dermik	Benzoyl peroxide; antibacterial
Benzamycin	Dermik	Erythromycin, benzoyl peroxide; antibiotic, antibacterial
Desquam-X 5	Westwood Squibb	Benzoyl peroxide; antibacterial
Double Ice ArthriCare Gel	Commerce	Menthol, camphor, liniment
Estar Gel	Westwood Squibb	Coal tar; antipsoriasis
Flex-all 454 Gel	Chattam	Menthol, methyl salicylate; liniment
Lidex Gel	Syntex	Fluocinonide; anti-inflammatory
Ordor Free ArthriCare Rub	Commerce	Menthol, methyl nicotinate, capsaicin; liniment
Persa-Gel	Ortho Derm	Benzoyl peroxide; antibacterial
Pilopine HS	Alcon	Pilocarpine HCl; miotic
PrameGel	GenDerm	Pramoxine HCl; antipruritic
Topicort Gel	Hoecht Marion Roussel	Desoximetasone; anti-inflammatory

gelling mechanism of poloxamers, where micelle-like junction zones form at or above room temperature. The junction zones consist of large populations of micelle-like structures, which apparently form a viscous, liquid crystalline phase (91, 92). Poloxamers can also form gels in dilute hydroalcoholic solutions.

Poloxamer gels have many characteristics favorable for use as artificial skin, which is helpful in treating third-degree burns. The gels are nontoxic, enhance healing by controlling water, heat, and electrolyte loss, and provide detergent activity on wound debris (93). Because of poloxamer's inverted thermoreversibility, cool solutions can be poured onto damaged tissue, forming gels when warmed to body temperature. The gels are easily removed by rinsing with cool water.

Poloxamer gels mimic mucus and are optically clear, which makes them suitable for ophthalmic drug delivery. A poloxamer gel formulation containing pilocarpine showed improved bioavailability over an aqueous solution of the drug (94). Release kinetics of lidocaine (91), diclofenac (95), and hydrocortisone (95) from topical poloxamer gels were also assessed. Subcutaneous injection of insulin loaded poloxamer gels prolonged the hypoglycemic effect of insulin in rats (95). Commercial topical gels include AquaTar (Allergan Herbert), a poloxamer-407 base that contains coal tar, and Benzac W (Galderma), a blend of poloxamer-182 and carbomer-940 gels, that contains benzoyl peroxide.

Polyacrylamide

Polyacrylamide (PAAm) is a hydrophilic polymer that absorbs and retains large volumes of water. However, aqueous solutions of PAAm, especially the high molecular weight species, undergo physical aging, which results in a decrease in viscosity. PAAm is soluble in hydrophilic nonaqueous liquids such as glycerol, but insoluble in methanol and ethanol.

Polyacrylamide forms water-based gels at concentrations around 4% w/v, which exhibit pseudoplastic behavior. A PAAm ophthalmic gel containing pilocarpine was compared with other gel vehicles; the ocular bioavailability for the PAAm gel was three times greater than that of the aqueous control solution (97). The kinetics of ibuprofen release for crosslinked PAAm gels was studied (98). A kinetic model was proposed for swelling induced loading of insulin into crosslinked PAAm gels (99).

Polyvinyl alcohol

Polyvinyl alcohol (PVA) is a hydrophilic, synthetic polymer that is prepared indirectly by hydrolyzing polyvinyl acetate. It cannot be produced by direct polymerization of vinyl alcohol because the monomer is

unstable (100). The chemical structure of PVA is simple, consisting of a carbon-chain backbone with alternating hydroxyl groups; it favors the formation of crystalline aggregates in solutions, gels, and solids. PVA is soluble in water, glycerin, and mixtures of water with the lower alcohols; however, it can be precipitated from aqueous solutions with sulfates and phosphates. The gelation of PVA occurs in more concentrated solutions; the gel point of 10% PVA in water is around 14°C (101). In general, gel strength depends on the degree of crystallinity of a particular sample.

Polyvinyl alcohol is used in ophthalmic preparations, serving as a mucus mimicking (mucomimetic) agent in artificial-tear formulations such as Liquifilm Tears and Liquifilm Forte (Allergan). Physically crosslinked PVA hydrogels, prepared by low-temperature crystallization, were tested as vehicles for the rectal administration of indomethacin (102). Chemically crosslinked PVA hydrogels have been considered for soft contact lenses. Both, the molecular weight between crosslinks, M_c , and the mesh size between crosslinks, ζ , were used to characterize a covalently crosslinked polyvinyl alcohol gel (8) during evaluation of bovine serum albumin (BSA) release. PVA hydrogel nanoparticles loaded with albumin into polylactic/glycolic acid microspheres released albumin up to two months (103). The release of water-soluble pseudoephedrine was studied from compressed swellable-soluble PVA matrices (104).

Inorganic Substances

Aluminum hydroxide

Aluminum hydroxide forms a two-phase gel consisting of a network of discrete solid particles in water. Aluminum hydroxide gels are soluble in acidic and extremely basic media, and are compatible with many additives, including glycerin, saccharin, and some preservatives (105).

The aluminum hydroxide gel exhibits thixotropic behavior. In addition, gel stability is enhanced by polyols such as mannitol and sorbitol (106). However, unlike other gels, aluminum hydroxide gels do not have demulcent properties; they are used mainly as an oral antacid preparations.

Smectite clays

Bentonite and hectorite clays consist primarily of hydrated aluminum and magnesium silicates, respectively. Bentonite is recognized for its swelling capacity; one gram can absorb up to 11 ml of water. A commonly used smectite clay is aluminum magnesium silicate (Veegum, R.T. Vanderbilt Co.). These clays have

plate-like particles, 1 to 2 μm in size, that form well-ordered gel mesophases spontaneously on contact with water. The gels are formed at about 5% concentration, and are presumably stabilized by opposite electrostatic charges between particle edges and faces (21). Therefore, these smectite gels are incompatible with strong electrolytes, and in particular with di- and trivalent cations. The gels also exhibit plastic flow; they have static yield values and are thixotropic.

Laponite clay also belongs to the smectite class, but is a synthetic gelling agent. Like bentonite, laponite swells considerably in water—but only a 2% concentration is needed to form a gel. Laponite does not contain impurities, which is an advantage over the natural clays; however, some electrolyte must be included in the water to support the gel microstructure (107).

Smectite clays are used by the pharmaceutical industry as mainly suspending and thickening agents. Because of the net negative charge of these clays, cationic drugs can be adsorbed by an ion-exchange mechanism. Release of metronidazole from bentonite complexes was inhibited at acidic pH, but increased significantly at pH 7 (108). Simple gels containing hectorite and gelatin were investigated for rectally administering insulin to rabbits (109). Finally, the iontophoretic transdermal transport of calcium from a paste of calcium-enriched bentonite was studied using excised pig skin (110).

GENERIC DRUGS AND GENERIC EQUIVALENCY

Arthur H. Kibbe

Wilkes University, Wilkes-Barre, Pennsylvania, U.S.A.

INTRODUCTION

All drugs that are approved for sale generally carry at least two names. The drugs are given a proprietary or trade name given by the company that first develops them. These companies often are referred to as the innovator company. The drug is assigned a nonproprietary or generic name, which is agreed to by the WHO International Nonproprietary Nomenclature (INN) Committee and the U.S. Adopted Names Council (USAN). A new drug is usually first marketed with some patent protection and at a price that, at a minimum, recoups the cost of development over the remaining life of the patent or other exclusivity arrangement. Eventually, protection from competition is lost to other pharmaceutical companies, often companies or divisions of companies that specialize in marketing off-patent drugs. These companies or divisions are called generic companies. They can apply to the appropriate regulatory body such as the Food and Drug Administration (FDA) for permission to market the same active ingredient under its nonproprietary or generic name. The generic manufacturer is not required to do a complete clinical trial to prove effectiveness and safety because that has already been well established for the drug. However, it is required to show that the new drug product is equivalent to the original drug product. For the purposes of this article, we define the drug as the chemical that has the pharmacological effect and the drug product as a dosage form that contains the drug and other ingredients or excipients that allow the formulation of the dosage form. There is a large economic incentive for the development of generic drug products, especially for highly successful drug products. The pharmaceutical company that first brought the product to market maintains the price at the original level or higher to continue the cash flow into the company. This allows the other companies to develop a formulation of the drug and to win approval to market with the knowledge that, even at a fraction of the selling price of the innovator's product, the company can make a good profit. Some innovators defend their market share by arguing quality and reliability. The FDA must act as an impartial arbitrator of this debate. The debate is clearly about money, but is argued in a scientific forum. The key question is, "Are we

sure that the two products, if used in the same way in the same patient, will yield the same result." If a drug product is subject to this debate, the innovator always says "no" and the second and subsequent manufacturers always say "yes." In the United States, the FDA sets the standards against which the question is resolved, and scientists take sides usually on the issue of "are the current FDA standards good enough." If the FDA gives an "A" rating to a drug product, it is in effect telling the prescriber that the drug product will yield the same therapeutic and side-effects profile as the innovator drug product. The Orange Book specifies the equivalence rating from the FDA. Almost all generic drug products currently marketed are rated A; the FDA has not approved a generic without an A rating in decades. Finally, the consumer pays the price, either in the unnecessarily high cost of drugs if unnecessary studies are performed and generic competition delayed or in risky drug substitution if the FDA is too relaxed in its standards. The tests required by the FDA have changed over the years. They have become more proscriptive and are based on sound statistical grounds. The FDA has also increased the level of oversight of the pharmaceutical companies that manufacture generic equivalents of innovator products. Thus, the regulatory process has become more stringent, and the level of assurance that the public has that a generic product is both safe and effective has gone up. The FDA has often stated that there are no known therapeutic failures from switching among products that have been ruled as equivalent by the FDA.

LEGISLATIVE AND REGULATORY HISTORY

In the early 1970s, most states had ant substitution laws that required the dispensing of the innovator product when the prescriber wrote for a drug by trade name. Most physicians had learned only the trade name of the drug product, and these laws ensured that generic substitution would be at a minimum (1). The American Pharmaceutical Association (APhA) along with other groups pushed for the repeal of these laws and opened the way for the growth

of the generic industry. The lack of bioequivalence data available at that time led to the formation of the Generic Drug Bureau within the Food and Drug Administration. As a result of the efforts of that group, the FDA produced a book, *Approved Drug Products With Therapeutic Equivalence Evaluations*, in the late 1960s. This became known as the Orange Book because of the cover color. The book has been published annually with monthly updates. The contents are now available on the FDA Website (2).

In 1984, the Drug Price Competition and Patent Term Restoration Act was passed. This act, also known as the Waxman–Hatch Bill of 1984, encouraged the development of new innovative drugs by established procedures, extended patent rights, and facilitated the FDA approval process for generic drugs (3). To address the first goal, the law created a mechanism to extend the period of patent protection for manufacturers of innovative new drugs generally ensuring at least 5 years of market exclusivity after approval. To address the second goal, the law established an Abbreviated New Drug Application (ANDA) for applications after 1962. Drugs chemically equivalent to those previously approved by a full application process need only be proven bioequivalent, not clinically equivalent. Depending on the drug, proof of bioequivalence can involve in vitro dissolution studies, in vivo single-dose bioavailability studies, in vivo multidose bioavailability studies, or a combination of these. However, in vitro dissolution studies alone are not adequate proof of bioequivalence for purposes of an ANDA.

SCIENTIFIC BASIS FOR GENERIC DRUG PRODUCT EQUIVALENCY: BIOAVAILABILITY–BIOEQUIVALENCY

The goal of the testing of generic products is not to establish the clinical usefulness of the drug but only to ensure that the generic product or new formulation has the same relative bioavailability as or is bioequivalent to the innovator product.

Bioavailability has been defined as a measure of the rate and extent of absorption of a drug into the systemic circulation after administration of a dosage form. An intravenous i.v. dose is considered by definition to be 100% bioavailable. All other routes of administration will produce a total bioavailability less than or equal to that of the i.v. dose. Thus, only a drug that is completely absorbed into the systemic circulation can have the extent of bioavailability equal to the dose stated on the label. In addition to the extent of absorption, the rate of absorption

plays a key role when evaluating the potential therapeutic impact of a particular dosage form. Knowledge of the time to onset of drug action, which is directly related to rate of absorption, is a significant concern, especially in acute clinical situations such as asthma attack, hyperglycemic shock, and pain.

The bioavailability of drugs from specific dosage forms is affected by the nature of the inactive ingredients or pharmaceutical excipients and the process used in its formulation. (For additional information, see Bioavailability of Drugs and Bioequivalency in this Encyclopedia.) When comparing similar dosage forms from different manufacturers or different lots from the same manufacturer, it is most useful to determine the relative bioavailability of the two products or lots. Some scientists have attempted to establish an in vitro test that could successfully predict in vivo bioavailability. However, to date, none has been developed.

Pharmacokinetics means the application of kinetics to drugs. It can be defined as the study of the time course and fate of drugs in the body. Teorell is often given credit for the origin of pharmacokinetics with his publications, *Kinetics of Distribution of Substances Administered to the Body* (4, 5). This science is the theoretical support for the use of bioequivalency testing to establish therapeutic equivalence among dosage forms of the same drug. The first approach to a pharmacokinetic understanding of drugs in the body, called compartment analysis, considered the body as a group of compartments through which the drug must pass. The compartment itself does not exist but represents the average of many processes that give rise to the observed phenomenon. The size of the imaginary compartment can be calculated and is useful in understanding the process of absorption, distribution, and elimination or metabolism of the drug. Regardless of the model used, a plot of the plasma concentration of the drug versus time yields a curve that can be described by a polyexponential equation. The area under that concentration–time curve (AUC) is directly related to the amount of drug absorbed. The time to reach peak concentration and the peak concentration itself are related to both the dose and the rate of absorption.

An important limitation of compartment analysis is that it cannot be applied universally to any drug. A simpler approach that is useful in the case of bioequivalency testing is the model independent method. It is based on statistical-moment theory. This approach uses the mean residence time (MRT) as a measure of a statistical half-life of the drug in the body. The MRT can be calculated by dividing the area under the first-moment curve (AUMC) by the area under the plasma curve (AUC) (6).

(See other articles in this Encyclopedia for more detailed discussion of these subjects.)

MEASUREMENT OF RELATIVE BIOAVAILABILITY OR BIOEQUIVALENCY

Drug products often undergo bioavailability testing in the early stages of development. Changes in formulation necessitated by results of clinical trials or stability testing or changes in the availability of excipients or changes in suppliers of excipients often require that the manufacturer perform a relative bioavailability or bioequivalency test to ensure that subsequent lots of a product will yield the same amount of active ingredient at the same rate as was possible in earlier formulations.

Bioequivalency studies are usually performed on young, healthy, male adult volunteers under controlled dietary conditions and fixed activity levels. This is because the goal of the study is not to establish the clinical usefulness of the drug but only to ensure that the two formulations have the same relative bioavailability or are bioequivalent.

Key Parameters

When assessing bioequivalence, the following three parameters that characterize the plasma or blood concentration–time profile of the administered drug are usually measured:

1. Peak height, C_{\max} , represents the highest concentration of the drug in the systemic circulation;
2. Time to peak, t_{\max} , represents the time for peak height to occur after the drug was administered;
3. Area under the curve, AUC, represents the total integrated area under the concentration–time curve.

The first two parameters are indicators of absorption rate, whereas the third is directly proportional to the extent of drug absorbed into the systemic circulation from the dosage form. Figure 1 is an example of a concentration–time curve for a single dose of drug to a subject.

Although it is theoretically possible to determine the rate and extent of absorption of a drug by measurement of the rate and extent of the appearance of the drug in the urine, this is not considered as reliable a method for evaluation of a drug product's bioequivalency as are blood level data. Thus, the studies commonly performed to demonstrate bioequivalence fall into two categories: single-dose and multidose or steady-state studies. There are advantages and disadvantages to each. Single-dose studies are less expensive and expose healthy volunteers

Fig. 1 Blood concentration curve.

to less drug during the course of the study. However, these studies require more sensitive analytical methods and have higher subject-to-subject variability. In both cases, a cross-over study design is used to control for sequence effects. The study is designed to control for or take into account as many variables as possible. The subjects are randomly assigned to groups. Blood samples are obtained from each subject before dosing and at fixed time intervals after dosing. Currently, the data are then analyzed using appropriate statistical ANOVA. The results must meet FDA guidelines for mean and 90% confidence interval for each of the three key parameters. For oral solid dosage forms, the FDA requires that for a product to be considered bioequivalent, the ratio of the parameter for the two products, together with their 90% confidence interval, must fall between 0.8 and 1.25, using log-transformed data. This, in effect, means that drug products that differ by more than 10% in their rate and extent of absorption will not be approved as generic equivalents.

CURRENT SCIENTIFIC ISSUES

Two issues have been raised recently with regard to the approval of generic drugs. The first has to do with the issue of "Narrow Therapeutic Index Drugs," and the second has to do with the use of individual bioequivalence in place of average bioequivalence. The former concern has been addressed in detail by Drs. Benet and Goyan (7). They concluded that narrow-therapeutic-range drugs were the least likely to have therapeutic failures among generic

drugs, with proof of bioequivalency. The use of average bioequivalence data is under attack. This is because of the concern that there might be a significant subject-by-product interaction. Regulatory agencies now assume that this is not the case (8). The advantage of using individual bioequivalence studies is the reassurance that if subject/product interactions do occur, the study design would control for them, and a more statistically valid measure of the rate and extent of absorption of the drug from the two product would be determined. Some of the disadvantages associated with shifting from average to individual bioequivalence testing are cost, numbers of subjects needed, and diversity of the study population required. [See other articles that address the impact of the new metrics on the reliability and cost of the performance of bioequivalence testing (9–12).]

THE CHANGING POLITICAL ECONOMY OF GENERIC DRUGS

The modern generic drug industry in the United States really only dates from the passage of the Waxman–Hatch Act in 1984. Within 5 years of passage, generic drugs captured 40% of the market for prescriptions written in the United States. Since that time, the generic drug market share has stabilized between 40 and 50% of the prescriptions written. However, the dollars paid for generic drugs are only 10% of the total sales of drugs in the United States. That statistic alone tells us that the consumer receives enormous benefit from the substitution of therapeutically equivalent generic drugs when available.

A horrendous scandal hit the industry in the late 1980s, wherein firms representing 75% of the production of the generic industry pled guilty to one or more criminal charges involving filing false applications with the FDA, paying illegal gratuities to FDA personnel, and/or related crimes to gain an unfair competitive advantage in the emerging marketplace. Surprisingly, this scandal produced only a small delay in the market share march of generic drugs and only a temporary loss of consumer confidence in generic products.

The scandal was tied to a phenomenon that still dominates the business strategies of generic drug firms to this day: the need to obtain approval to manufacture and distribute before other firms enter the market. Because of the “commodity” nature of the business and the relative ease of entry into the industry, firms devote most of their resources and managerial talent to obtaining first or second approvals from the FDA for their products. Once a generic

drug has four or more competitors, it is no longer profitable for additional generic companies to enter the market.

Generic drug manufacturers typically will continue to manufacture drugs that produce little or no profit because large purchasers that are their prime customers (chain drugs stores, buying groups for smaller community pharmacies, etc.) prefer to buy from companies that can supply most of the common generic drugs. For example, if a generic drug firm no longer produces amoxicillin because it can make more money by shifting its antibiotic production facilities to, for example, a cephalosporin drug for which it has less competition, a large chain may choose to buy its entire generic antibiotic line from another company that supplies both.

The profitable generic drug companies are profitable because they have found a strategy to maintain some control over the price of their products. In the early years (1984–1988), the best way to get “first approval” from the FDA apparently was to be first to file, to get assays or bioequivalence studies done on difficult to duplicate drugs, or to find some way to get an expedited approval from inside the agency. Unfortunately, this sometime involved payoffs to FDA review chemists (those FDA experts assigned the task of evaluating biostudy results, the crucial piece of a generic drug application, remained remarkably free of the scandal). More often, it involved submitting false information to the FDA (including, in a few cases, false biostudies). Many generic drug firms did not survive the scandal, and others survived only after the previous management and ownership were purged from the firms.

For a short period, it was believed that the profitable segment of the business involved not production but distribution. After all, if commodity prices approach marginal cost and the marginal cost of manufacturing drugs is minimal, but the price to the consumer remains significantly more than marginal, there must be middlemen somewhere making the money. Clearly, those middlemen were not in the retail pharmacy where profits continued to be squeezed. Distributors were thought to be the new profit centers. But a funny thing happened on the way to that particular bank...

Consumers became outraged at the rapid increase in the price of pharmaceuticals as the innovator companies (and some generic firms) rushed to raise prices and as generic drug company after generic drug company was pushed out of the industry in the wake of investigations by a Congressional committee and a federal grand jury. Second, the Administration, in response to public concern about the cost of pharmaceuticals, pressured the pharmaceutical industry and forced lower prices and significant rebates to the federal and state government

programs that paid for drugs. Wholesale distributors of all drugs subject to the federal rebates suffered.

Finally, the firms that thought they could profit most from the scandal entered the market. These were innovator firms, many of which had already played a significant role in the distribution of generics. Ultimately, the profit margins from generic drug sales were not sufficient to carry the overhead of the branded companies, and most left the market or returned to their distributor role. Even in the case of the firms manufacturing and marketing generic versions of their own branded products, giving them significant advantage over the remaining pure generic firms in developing and filing of the ANDAs with the FDA and the added advantage of relatively less scrutiny from the scandal-rocked agency, most had exited the marketed by the end of the decade.

Some innovator firms entered the generic drug market so that they could have a product line consistent with their new business strategy: disease state management. This strategy, a function of the rise of HMOs and the return of the concept of scarcity to prescription drug dispensing, was intended to involve the development of a continuum of drug therapies for the treatment of a specific illness (diabetes, depression, etc.), wherein the patient would be tried on the older, less-expensive drug first and, if it did not work, the next most cost-effective drug would be administered and so on until the least cost-effective drug would be the treatment of last resort. Unfortunately, the branded companies that selected this strategy found themselves competing with doctors, hospitals, and insurance companies for control of the treatment regime of individual patients, a losing proposition for the entity with the least amount of information about and access to the individual patient.

Another factor in reducing prices of all drugs that had some form of competition was the rise of the HMO and its pharmaceutical watchdog, the pharmacy benefit manager (PBM). These PBMs create a formulary of approved drugs (drugs for which they would reimburse partially or fully) based on bids from competing companies.

Much of the public's confusion regarding generic drugs arose from a practice of the PBMs to pressure doctors to substitute different chemical entities in the same therapeutic class for the prescribed medicine. Such a switch is called a therapeutic substitution as opposed to the switching among manufacturers of therapeutically equivalent drugs (generics and the innovator drug or other FDA "AB"-rated substitutes). Therapeutic substitution involves a switch to a different drug, whereas generic substitution involves a switch to the same drug from a different manufacturer. If a patient is switched

between FDA "AB"-rated drugs, the FDA offers the assurance that they can expect the same therapeutic and side-effect profile as the brand drug or another "AB"-rated generic drug. The FDA offers no such assurance if the switch occurs among different drugs, even if they are in the same therapeutic class. For example, aspirin and Tylenol may be equally effective in the treatment of headache, but the FDA makes no such certification, whereas it makes exactly that certification for Bayer aspirin and Safeway aspirin.

The dominance of the HMO (and related organizations) and their PBMs (and related organization types) served to accelerate the substitution of generic drugs at the turn of the 21st century. However, even that pressure could not slow the re-emergence of a high rate of price increase, greater than consumer or comparable wholesale prices as a whole, in prescription drugs. Innovator companies learned that establishing very high prices for "breakthrough" drugs could more than compensate for the loss of patent protection on a highly profitable drug.

Furthermore, the United States is the only developed country in the world that has chosen not to explicitly control the price of any drug product and has used its market power as a huge buyer relatively sparingly. Consequently, U.S. prices for drug products still under patent are usually substantially above those charged anywhere else in the world. Generic prices approach cost except for those few generics that have managed to eliminate or limit for a specific period competition from other generics.

Those generic drug firms that prospered in this restrictive price environment all had one or more niche drugs that were immune from corrosive price competition. Some companies mastered a manufacturing process that produced bioequivalent medicine that the innovator itself found difficult to master lot to lot. Others took advantage of certain exclusivity provisions in the law for those that challenged a product patent in court, ostensibly to cover the cost of litigation. In other cases, the settlement of those cases provided some form of licensing or distribution rights that permitted the sale of a generic product while the patent was still valid. Finally, a fortunate firm might find itself in possession of the exclusive right to purchase the raw material from the only source available to generic drug manufacturers.

All generic drug firms capable of generating the necessary cash to develop and market new drugs are moving toward that lucrative market. For the time being, the United States has chosen to use the market mechanism as its only important control on drug prices. Generics are the competition, and competition is our only real form of price control.

According to the Congressional Budget Office (CBO), consumers saved \$8–10 billion in 1994 because of the use of generic drugs. In that same 1998 report, CBO cited the Waxman–Hatch Act, generic substitution laws passed by the states, and government health programs as seminal events leading to the acceptance of generic drugs and the resulting savings.

FREEZE DRYING

Michael J. Pikal

University of Connecticut, Storrs, Connecticut, U.S.A.

INTRODUCTION

Freeze drying, also termed “lyophilization,” is a drying process employed to convert solutions of labile materials into solids of sufficient stability for distribution and storage. A typical production scale freeze dryer consists of a drying “chamber” containing temperature-controlled shelves, which is connected to a “condenser” chamber via a large valve. The condenser chamber houses a series of plates or coils capable of being maintained at very low temperature (i.e., less than -50°C). One or more vacuum pumps in series are connected to the condenser chamber to achieve pressures in the range of 0.03–0.3 Torr in the entire system during operation. A commercial freeze dryer may have 10–20 shelves with a total load of the order of 50,000 vials. The objective in a freeze-drying process is to convert most of the water into ice in the *freezing stage*, remove the ice by direct sublimation in the *primary drying stage*, and finally remove most of the unfrozen water in the *secondary drying stage* by desorption. The water removed from the product is reconverted into ice by the condenser.

In a typical freeze-drying process, an aqueous solution containing the drug and various formulation aids, or “excipients,” is filled into glass vials, and the vials are loaded onto the temperature-controlled shelves. The shelf temperature is reduced, typically in several stages, to a temperature in the vicinity of -40°C , thereby converting nearly all the water into ice. Some excipients, such as buffer salts and mannitol, may partially crystallize during freezing, but most “drugs,” particularly proteins, remain amorphous. The drug and excipients are typically converted into an amorphous glass also containing large amounts of unfrozen water (15–30%) dissolved in the solid (i.e., glassy) amorphous phase. Thus, most of the desiccation actually occurs during the freezing stage of the freeze-drying process. After all water and solutes have been converted into solids, the entire system is evacuated by the vacuum pumps to the desired control pressure, the shelf temperature is increased to supply energy for sublimation, and primary drying begins. Due to the large heat flow required during primary drying, the product temperature runs much lower than the shelf temperature.

The removal of ice crystals by sublimation creates an open network of “pores,” which allows pathways for escape of water vapor from the product. The ice–vapor boundary (i.e., the boundary between frozen and “dried” regions) generally moves from the top of the product toward the bottom of the vial as primary drying proceeds. Primary drying is normally the longest part of the freeze-drying process. Primary drying times of the order of days are not uncommon, and in rare cases, weeks may be required for a combination of poor formulation and suboptimal process design. Although some secondary drying does occur during primary drying (i.e., desorption of water from the amorphous phase occurs to a limited extent once the ice is removed from that region), the start of secondary drying is normally defined, in an operational sense, as the end of primary drying (i.e., when all ice is removed). Of course, because not all vials behave identically, some vials enter secondary drying whereas other vials are in the last stages of primary drying. When the judgment is made that all vials are devoid of ice, the shelf temperature is typically increased to provide the higher product temperature required for efficient removal of the unfrozen water. The final stages of secondary drying are normally carried out at shelf temperatures in the range of 25 – 50°C for several hours. Here, because the demand for heat is low, the shelf temperature and the product temperature are nearly identical.

As freeze-drying plants are very expensive and process times are often long, a freeze-dried dosage form is relatively expensive to produce. Indeed, because of both cost and ease of use, a ready-to-use solution is the preferred option for a parenteral dosage form, particularly if the solution can withstand terminal heat sterilization. When an aqueous solution does not have sufficient stability, the product must be produced in solid form. At least for small molecules, stability normally increases in the following order: solution < glassy solid < crystalline solid (1–3); this is likely a result of restricted motion in solids with the high degree of order in the crystalline solid limiting reactivity even further. As many pharmaceuticals cannot be produced on a commercial scale by crystallization, a glassy solid may be the only solid-state option.

Freeze drying (4–7) and spray drying (8–10) are drying methodologies in common use in the pharmaceutical industry, and are suitable for the production of glassy solids. Freeze drying is a low-temperature process. In general, a formulation can be dried to 1% water or less, without any of the product exceeding 30°C. Thus, conventional wisdom states that freeze-drying is less likely to cause thermal degradation than a high-temperature process such as spray drying. Historically, freeze-drying is the method of choice for products intended for parenteral administration. Sterility and relative freedom from particulates are critical quality attributes for parenterals. Largely because the solution is sterile filtered immediately before filling into the final container, and further processing is relatively free of exposure to humans, a freeze-drying process maintains sterility and particle-free characteristics of the product much more easily than do processes that must deal with dry powder handling issues, such as dry powder filling of a spray-dried or bulk-crystallized powder. Indeed, with modern robotics automatic loading systems (11), humans can be removed from the sterile processing area entirely, at least in principle. Furthermore, as the vials are sealed in the freeze dryer, moisture control and control of headspace gas can easily be controlled, an important advantage for products whose storage stability is adversely affected by residual moisture and/or oxygen. As the critical heat and mass transfer characteristics for freeze-drying are nearly the same at the laboratory scale as in full production, resolution of scale-up problems tends to be easier for a freeze-drying process than for spray drying, at least in our experience. Also, development of a freeze-dried product requires less material for formulation and process development, a particularly important factor early in a project.

While freeze-drying has a long history in the pharmaceutical industry as a technique for stabilization of labile drugs, including proteins, many proteins suffer irreversible change, or degradation, during the freeze-drying process (12–16). Even when the labile drug survives the freeze-drying process without degradation, the resulting product is rarely found perfectly stable during long-term storage, particularly when analytical techniques with a sensitivity to detect low levels of degradation ($\approx 0.1\%$) are employed. Both small molecules (1–3, 17) and proteins (18–21) show degradation during storage of the freeze-dried glass. In some cases, instability is serious enough to require refrigerated storage (18, 19, 22).

Stability problems are most often addressed by a combination of formulation optimization and attention to process control. Lyoprotectants are added for stability during the freeze-drying process as well as to provide

storage stability, and the level and type of buffer is optimized. Optimization of the freezing process may be critical; control of product temperature during drying is critical for products that tend to suffer cake collapse during primary drying, and control of residual moisture is nearly always critical for storage stability. Formulation and process are interrelated: A bad formulation can be nearly impossible to freeze dry, and even with a well designed formulation, a poorly designed process may require more than a week to produce material of suboptimal quality. Although blind empiricism may, in time, yield an acceptable formulation and process, an appreciation for the materials science of amorphous systems and some understanding of heat and mass transfer relevant to freeze-drying are needed for efficient development of freeze-dried products. Obviously, one also requires at least a phenomenological understanding of the major degradation pathways specific to the drug under consideration.

The objective of this article is to present the scientific and engineering fundamentals most useful in the development of formulations and processes for the manufacture of freeze-dried pharmaceuticals. Generalizations are illustrated with specific examples from the literature, but no attempt is made to survey all published works. Most of the section on the freeze-drying process applies equally well to small molecules and proteins, whereas most of the section on formulation and stability is specific to proteins.

THE FREEZE-DRYING PROCESS

Freezing

Freeze concentration

The objective of freezing is to remove most of the water from the system by formation of ice and to convert all solutes into solids, either crystalline solids or a glass. Once the sample is a solid, primary drying may begin. As a sample is cooled, the system remains liquid well below the equilibrium freezing point, but with sufficient supercooling, nucleation of ice proceeds rapidly and growth of ice crystals begins. As liquid water converts to ice, all solutes are concentrated in the regions between ice crystals, ultimately concentrating until they crystallize or until the system increases in viscosity sufficiently to transform into a solid amorphous system, or glass. The example shown in Fig. 1 is representative of a solute that does not crystallize during freeze-drying. The system supercools about 10°C to a temperature of -15°C before ice nucleation becomes rapid enough to generate crystals

Fig. 1 Freeze concentration in an amorphous system. The product temperature is shown as a broken line whereas the percentage of unfrozen water is shown as a solid line. (From Ref. 6.)

of ice. The evolution of heat caused by the sudden crystallization of ice increases the sample temperature to roughly the equilibrium freezing point (-5°C). The sudden ice crystallization also results in a small but sharp decrease in the percentage of water in the solute phase (given on the right vertical axis). After the initial ice nucleation and crystallization at 10 min, the product cools with continuous conversion of water to ice, thereby decreasing the amount of water in the solute phase and increasing the concentration of solute in the remaining solution. When the product temperature reaches about -24°C , denoted as T_g' , the concentration of water in the solute phase has been reduced to about 24%, and further reduction in water concentration is curtailed on the time scale of freezing, even though the sample temperature decreases further to about -30°C at the end of the freezing process at 60 min. Here, the solute phase has been concentrated from about 30% solute to about 76% solute, and most of the water has been separated from the solute phase as ice. Had the initial concentration been much lower, say 1%, the final concentration would still be 76%, although the freezing profile would differ quantitatively from that shown in Fig. 1. Clearly, most of the desiccation in a freeze-drying process occurs during the freezing process. While desiccation is indeed the objective, it must be recognized that concentration of all solutes during freezing will dramatically increase the probability of

bimolecular collisions, which could produce unexpected instability in the partly frozen system. If a system, initially at 1% solute, is susceptible to a second-order degradation reaction with an activation energy of 25 kcal/mol, a reduction in temperature from 5°C to -24°C would reduce the rate constant by a factor of 200, but an increase in concentration from 1% to 76% would increase the concentration factor in the rate equation by a factor of 5800, yielding a factor of 29 net increase in reaction rate. Although this example is an oversimplification, it is significant to note that increases in second-order degradation rates have been observed in model systems during freeze concentration (23).

T_g' is the temperature at which a sharp increase in baseline occurs during a differential scanning calorimeter (DSC) scan of a frozen solution, suggesting a sharp increase in heat capacity, and has been referred to as the glass transition temperature of the maximally concentrated freeze concentrate (24). A sharp decrease in electrical resistance of the frozen system is noted at the same temperature (25). Structural collapse of a cake structure in the dried region, indicating viscous flow, occurs during primary drying at the collapse temperature, denoted by T_c , which is only slightly higher than T_g' (25). It is clear that T_g' corresponds to the temperature at which mobility in the system is manifested on an experimental timescale. Effectively, the system behaves as a solid below T_g' .

Various electrolytes, such as buffer salts and NaCl, if present in the formulation, will also concentrate during the freezing process. Such exposure to high concentrations of electrolytes (i.e., about 6 molal NaCl during freezing a 0.15 M NaCl solution) might contribute to the destabilization of the native conformation, thereby leading to degradation during freezing.

Crystallization of excipients and consequences

In the case of protein drugs, the drug does not crystallize, but other solute components may (or may not) crystallize, depending on their nature and concentration, other formulation components, and the details of the freezing process. High initial concentrations and slow freezing tend to favor crystallization. Depending on the intended role of the excipient, crystallization may be desirable or undesirable, and it may be important just when in the process crystallization does occur. For example, if mannitol is intended only as a bulking agent, and is not expected to play a role in stabilization of the drug, crystallization is desirable as crystalline mannitol can easily be freeze dried at high temperatures to give an elegant product, meaning a short freeze-drying cycle and freedom from product defects such as collapse. Here, the drug form is that of an amorphous coating on the

crystalline mannitol, with stability properties normally close to that of a system freeze dried without the mannitol. If mannitol remains amorphous during freezing and crystallizes as the product temperature is increased in early primary drying, extensive vial breakage can occur (26). Conversely, if mannitol is intended to serve as a stabilizer during drying and/or storage, crystallization is undesirable. Complete crystallization yields a system equivalent to a physical mixture of glassy drug particles and crystalline mannitol, with no opportunity for a stabilizing interaction except at the phase boundary between the particles, no dilution of drug molecules, and no separation of "reactants" in the protein phase from the protein molecules. In short, any plausible stabilization mechanism requires that at least some of the mannitol remain molecularly dispersed in the amorphous drug phase. Of course, just as crystalline mannitol has some solubility in any liquid, mannitol will have a nonzero thermodynamic solubility in the drug phase. Thus, even if mannitol crystallization proceeds to thermodynamic equilibrium, a small amount of mannitol will remain in the drug phase. However, most of the stabilization potential of the mannitol will be lost upon crystallization. As mannitol does tend to crystallize nearly completely when present as the major formulation component, mannitol is generally a poor choice as a stabilizer for freeze drying.

Although buffers are included in a formulation to maintain constant pH, selective crystallization of the less soluble buffer component during freezing can result in massive pH shifts in the freeze concentrate. Figure 2 shows the pH changes observed during equilibrium freezing of several pure buffer systems (27). Freezing

Fig. 2 Shifts in pH during freezing arising from buffer salt crystallization. Near-equilibrium conditions were achieved by seeding with ice and salt. circles: sodium phosphate; squares: potassium phosphate; triangles: citrate. (Data from Ref. 27.)

was carried out while seeding with ice and crystalline buffer salts, so the data represent near-equilibrium behavior. Over the temperature range studied, the citrate buffer system showed no significant pH shift. The sodium phosphate buffer system shows a dramatic decrease in pH of about 4 pH units due to crystallization of the basic buffer component, $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$. Conversely, the potassium phosphate system shows only a modest increase in pH of about 0.8 pH unit. Under nonequilibrium conditions (i.e., no seeding) and with lower buffer concentrations, the degree of crystallization is less, and the resulting pH shifts are moderated (28). Table 1 shows data accumulated (29, 30) during freezing of phosphate buffer solutions in large volumes at cooling rates intended to mimic freezing in vials. For the concentrated buffer solutions (100 mM), the frozen pH values are close to the equilibrium values given in Fig. 2. However, lowering the buffer concentration by an order of magnitude considerably reduces the pH shift observed during freezing. It should also be noted that the small pH shift for potassium phosphate buffer noted in Fig. 2 is a result of the starting pH being 7.5. As shown in Table 1, if the initial pH is 5.5, the 100 mM potassium phosphate buffer increases by 3.1 pH units during freezing. In short, the frozen system pH is near 8.7, regardless of whether the initial pH is 7.0 or 5.5. Clearly, if drug stability is sensitive to pH shifts, buffer crystallization must be avoided. In our experience, the best solution is to formulate such that the weight ratio of buffer to other solutes is very low (18, 22). However, the precise meaning of "very low" varies with the nature and amount of the other solutes as well as with the nature of the buffer.

Instability during freezing and T_g'

Most small molecules are stable during the freezing process, even though storage stability may be marginal. Proteins show a wide range of formulation-sensitive instability. Some proteins survive freezing with little or no

Table 1 Shifts in pH during nonequilibrium freezing with phosphate buffer systems

Concentration (mM)	Initial pH	Frozen pH	Δ pH
Sodium phosphate buffer			
100	7.5	4.1	-3.4
8	7.5	5.1	-2.4
Potassium phosphate buffer			
100	7.0	8.7	+1.7
100	5.5	8.6	+3.1
10	5.5	6.6	+1.1

(From Refs. 29 and 30.)

measurable loss in activity, whereas others are irreversibly deactivated by the freezing process (12–21, 31–33). An environment quite different from a dilute aqueous solution is created during freezing. All solute species are dramatically concentrated, ionic strength increases, the pH may shift, and above all, hydrophobic interactions that stabilize the native conformation in water are reduced or eliminated as bulk water is removed from the protein phase. In addition, just as proteins undergo thermal denaturation at elevated temperature, proteins also undergo spontaneous unfolding at very low temperature, called “cold denaturation” (34, 35). Estimated cold denaturation temperatures are often below the T_g' of a protein formulation and therefore of questionable relevance to freeze-drying. However, these estimates are based upon thermodynamic parameters measured in dilute aqueous solutions. The impact of perturbations caused by freeze concentration is largely unknown.

Because of these many freezing stresses that may decrease the free energy of denaturation, thermodynamic destabilization of the native conformation during freezing is not surprising. Indeed, it appears surprising that all proteins do not spontaneously unfold and degrade during freezing. However, for a destabilized protein to unfold and engage in subsequent irreversible reactions, the rate of unfolding must be fast relative to the timescale of freezing. Even in dilute aqueous solution at room temperature, protein unfolding may involve time constants of the order of hours (36, 37). In the freeze concentrate approaching T_g' , at temperatures $\approx 30^\circ\text{C}$ lower than room temperature and viscosities about 10 orders of magnitude greater than in a dilute aqueous solution, one would expect greatly reduced unfolding rates, perhaps sufficiently reduced to prevent degradation during freezing. Kinetic studies of unfolding near T_g' would resolve this question. Unfortunately, such data are not available. However, it has been argued on theoretical grounds that rate processes, in general, should be slowed greatly as the system temperature approaches a glass transition temperature (33). Experimental studies of three different reactions in frozen maltodextrin systems lend support to this view, although not all reactions show the same strong temperature dependence near a glass transition (38). As a general rule, it would seem prudent to minimize the time a protein spends in a freeze concentrate above T_g' (i.e., minimize freezing time), and primary drying should be carried out near or below T_g' . However, these precautions do not always guarantee stability.

Optimum freezing rate

Frequently, the freezing process is characterized by specification of freezing rate, where in most cases it

is really the temperature change of the heat sink that is specified, or at best, the cooling rate of the solution is given. However, there are at least two freezing parameters that are needed to define the freezing process—the degree of supercooling and the rate of ice crystallization. The degree of supercooling is the difference between the equilibrium freezing point and the temperature at which ice crystals first form in the sample. The degree of supercooling determines the number of nuclei and, therefore, determines the number of ice crystals formed in the sample. A high degree of supercooling produces a large number of ice crystals, and as the total amount of water that freezes is fixed, the ice crystals produced after completion of freezing are small in size. Size of ice crystals impacts on process design and may also affect product quality, as will be discussed later. The rate of ice crystal growth determines the residence time of the product in a freeze-concentrated fluid state. A rapid growth rate minimizes the residence time, normally allowing less degradation during the freezing process. In practical freeze-drying applications, heat transfer limits the rate of ice growth. Therefore, in vials and pans where heat removal is through the container bottom, rapid ice growth is facilitated by a small fill volume to container area ratio (i.e., small fill depth) and good contact between the container bottom and the freeze dryer shelf. In general, rapid ice growth is also promoted by a low shelf temperature. However, if a warm vial with a large fill depth is placed directly on a very cold shelf, a very high degree of supercooling may be produced near the vial bottom before convective mixing cools the upper portion of the solution. Ice then forms near the vial bottom whereas the remainder of the solution remains completely liquid. Freezing then continues slowly from bottom to top as a freezing front. Such a freezing pattern normally produces a dried cake with two distinct structures: a region of very fine pores near the bottom, with most of the cake having very large pores due to the very large ice crystals that formed during advance of the freezing front. The product may be perceived as “lacking in elegance.” At the least, a process designed to produce a fast freeze gives instead a slow freeze.

A high degree of supercooling produces small ice crystals and small pore size in the dried layer, which results in a high resistance to water vapor transport during primary drying (39). Consequently, long primary drying times result. Small ice crystals also mean a high specific surface area in the dried product, which decreases secondary drying time (40). These trends suggest that a moderate degree of supercooling is optimal. While the size of ice crystals would not normally be expected to impact on product quality, it is clear that if a protein were to

denature at the aqueous ice interface, small ice crystals would mean a large interfacial area and more denaturation, perhaps leading to increased aggregation during freezing. There is now clear evidence that, at least in some cases, proteins may indeed denature at the aqueous-ice interface (41, 42).

In general, the optimum freezing process produces moderate and uniform supercooling and fast ice growth. Uniformity within a given vial avoids heterogeneous cake structure, and uniformity between vials minimizes variation in drying rates and sample temperatures. The combination of moderate supercooling and fast ice growth is difficult to achieve as, in usual practice, the cooling rate of the heat sink (i.e., the shelf) is the only controllable factor in freezing. A general procedure that normally gives satisfactory results may be summarized as follows. First, the product load is cooled to a temperature below the equilibrium freezing point but above the temperature where experience has demonstrated that ice nucleation does not occur (i.e., typically $\approx -5^\circ\text{C}$), and the load is equilibrated at this temperature for a short time (i.e., 15–30 min). Next, the shelf temperature is decreased quickly toward the final temperature (i.e., to -40°C at $\approx 1^\circ\text{C}/\text{min}$). At least with a small fill depth (≈ 1 cm), ice nucleation usually occurs uniformly with moderate supercooling, yet ice growth proceeds relatively rapidly. When product temperature is monitored with temperature sensors in selected vials, the time at which all measured product temperatures are below a given temperature (i.e., time when the product is several degrees above the final shelf temperature) is recorded. Since vials containing temperature sensors often freeze sooner than the batch as a whole (43), the product load is allowed to soak for a fixed time (about an hour) to allow all vials to “catch up” and reach the desired temperature at which all product is in the solid state.

Primary Drying

Mass transfer resistance, product temperature, and drying rate

The effect of product temperature and mass transfer resistance on sublimation rate may be mathematically illustrated (39, 44) by expressing the sublimation rate per vial, dm/dt , in terms of the driving force for transport of water vapor from the ice-vapor interface to the chamber, $P_0 - P_c$,

$$\frac{dm}{dt} = \frac{P_0 - P_c}{R_p + R_s} \quad (1)$$

where P_0 is the equilibrium vapor pressure of ice at the temperature of the frozen product, P_c is the pressure in

the drying chamber, R_p is the resistance of the dried product layer, and R_s is the stopper resistance. As P_0 increases exponentially with temperature, it is obvious that the driving force for sublimation, and, therefore, also the sublimation rate, increases dramatically as the product temperature increases (about a factor of two per 5°C increase in temperature). The decrease in primary drying time with increasing product temperature is illustrated by Fig. 3. These data represent calculations based upon integration of Eq. 1 for a hypothetical (but typical) product at both a small (0.5 cm) and large (2.0 cm) fill depths. The value of chamber pressure used varies due to an attempt to maintain the condition $P_0 \gg P_c$, but yet employ chamber pressures near the optimum range for uniform heat transfer (≈ 0.1 – 0.2 Torr) when possible (44). At the lowest product temperatures, the chamber pressures selected are well below the optimum for uniform heat transfer, but much higher pressures would give very long drying times. At each temperature, drying time is roughly proportional to the square of the fill depth, and target temperatures below -40°C become impractical for 2-cm fill depths.

It should be noted that Eq. 1 assumes that the gas in the vial is essentially 100% water vapor. Both theoretical and experimental evidence indicate that, during most primary drying conditions of practical interest, the gas in the vial and the gas in the drying chamber is nearly all water vapor, even when the chamber pressure is being controlled by an inert gas leak (44). The molar flow rate of inert gas (i.e., N_2) leaked into the drying chamber is generally much smaller than the molar flow rate of water

Fig. 3 Calculated primary drying times for a typical product as a function of product temperature. Open circles = 0.5-cm fill depth; filled circles = 2.0-cm fill depth.

vapor during primary drying, so the composition of gas in the drying chamber remains mostly water vapor. The inert gas “overwhelms” the vacuum pumps and, therefore, increases the total pressure in pumping system, which then causes a “back-up” of water vapor into the drying chamber.

Clearly, fast freeze-drying demands both high target product temperature and a small fill depth, which unfortunately is not always possible. To maintain product elegance, and in some cases to minimize degradation, primary drying must be carried out at product temperatures below the collapse temperature. As noted earlier, the collapse temperature and T_g' are closely related, with the collapse temperature normally being several degrees higher than T_g' . In practice, recognizing that not all vials freeze dry at exactly the same temperature, the target product temperature is chosen several degrees below the collapse temperature to provide a safety margin. A collapse temperature is a property of all components in the amorphous phase, and consequently the collapse temperature is highly formulation dependent (45, 46).

Although the product temperature is generally the most important factor in determining the rate of primary drying, product resistance is also an important parameter. The dried product resistance, R_p depends on the cross-sectional area of the product, A_p , by the relation $R_p = \hat{R}_p/A_p$, where \hat{R}_p is the area normalized product resistance, which is independent of the sample area but depends on both the nature of the product and the thickness of the dried product. Thus, R_p depends on the container used in that A_p is fixed by the internal diameter of the vial. The units used for \hat{R}_p (39, 44) are $\text{cm}^2 \text{ Torr hr g}^{-1}$. With this choice of units, the numerical value of \hat{R}_p represents the approximate time (in hours) to freeze dry a 1 cm thick sample at a temperature of -20°C , if the resistance would remain constant over the duration of primary drying. As one might expect, the resistance increases as the dry-layer increases in thickness, and therefore, resistance increases as primary drying proceeds. However, the relationship between resistance and thickness is not usually a direct proportion, although the resistance is often roughly linear in dry-layer thickness (39, 44).

Variation of product resistance with concentration is illustrated by the data in Fig. 4, where values of the mean product resistance, $\langle \hat{R}_p \rangle$, are given for various product types at different total solute concentrations. The mean product resistance is the mean resistance over a dry layer thickness interval of 0–1 cm. The scatter reflects formulation-specific effects whereas the general trend with increasing concentration illustrates the tendency of higher concentrations to produce higher resistance and therefore, longer drying times. A typical value for the

Fig. 4 Mean dry product resistance values for various products. Squares = proteins; filled circles = peptides; triangles = carbohydrates; open circle = pure ice; crosses (x) = miscellaneous types. (M.J. Pikal, Eli Lilly & Co., unpublished results.)

resistance of a small 13-mm finish stopper is shown as a straight line. Note that except for very dilute solutions, $R_p \gg R_s$.

Process control: Product temperature measurement

In most commercial freeze-drying processes, chamber pressure, shelf temperature, and time are the only controllable process parameters. Product temperature is not directly controlled. It is the balance between heat and mass transfer that determines the product temperature (47). Obviously, shelf temperature is important in determining the heat transfer and product temperature. However, because much of the heat is transferred through the gas phase (i.e., collisions of gas molecules with the hot shelf surface and the cold vial bottom), heat transfer as well as mass transfer (Eq. 1) is determined, in part, by the chamber pressure. Therefore, product temperature is determined by shelf temperature, chamber pressure, the heat-transfer characteristics of the vials, and the mass-transfer characteristics of the product and semistoppered vials.

Conventionally, product temperature is monitored in a small number of vials by placing temperature sensors at the bottom center of the vials. It is assumed that at least the average of the measured temperatures is representative of the rest of the vials. The trend in product temperature with time is often used to determine the end of primary drying. That is, when the measured product temperature shows a sharp increase near the anticipated end of primary drying,

and begins to approach the shelf temperature, it is assumed that all ice in that vial has been removed. Generally, for that vial, this assumption is correct. When all vials containing temperature sensors are judged dry by this criterion, one might be tempted to assume that all vials in the batch are dry. This assumption is not generally correct. Vials containing temperature sensors are not representative of the batch as a whole. There exists a temperature and drying rate bias between the monitored vials and the rest of the batch. Monitored vials usually freeze sooner with less supercooling than does the batch as a whole (43). This effect is particularly significant in production where due to the particle-free environment, the introduction of a temperature sensor introduces a significantly higher level of heterogeneous nucleation sites, thereby causing nucleation of ice at a lower temperature than in vials without temperature sensors. Observations made during a production run on moxalactam are illustrated in Fig. 5 (43). Monitored vials supercool to around -15°C and then begin freezing. The vials not monitored do not begin freezing until much later, at which time the product temperature must be close to the shelf temperature of -25°C . Thus, nonmonitored vials undergo a much greater degree of supercooling, have smaller ice crystals, smaller pores, more resistance to mass transfer, freeze dry at higher temperature, and require more time to dry than the rest of the vials. The temperature bias during primary drying is usually small, $\approx 1^{\circ}\text{C}$, but the drying time bias is 10% of the primary drying time, which can be quite significant for long primary drying times (43). To compensate for this bias in drying time, a soak period of 10–15% of the primary drying time is imposed following the time when all monitored vials are judged dry. Only after this soak period is the shelf temperature increased for

Fig. 5 Experimental observation of freezing bias: A production run of moxalactam di-sodium. (From Ref. 42.)

secondary drying. Premature increase of the shelf temperature carries a high risk of collapse. Thus, although monitoring the temperature of the product in vials does provide some information on the progress of primary drying, the information provided is far from perfect!

Location of the monitored vials in the vial array on the shelf is also an important factor in recording representative data. Vials on the edge of an array (i.e., facing the dryer door or walls) normally are not representative of the vials in the interior of an array, which are surrounded by other vials (44). Due to differences in radiative heat transfer, such vials normally dry faster at a higher temperature. With a shelf temperature around 5°C , temperature bias is about 1°C , with drying time bias about 10% (44), and the effect increases in magnitude as the difference between shelf temperature and ambient temperature increases and chamber pressure decreases. However, to minimize the risk of loss of sterility in surrounding vials, the temperature sensors are frequently placed in vials on the edge of the vial array facing the door. Again, the monitored vials are not representative of the batch as a whole. Clearly, minimizing the risk of product contamination with microorganisms is extremely important. From a sterility assurance viewpoint, the ultimate low-risk process is achieved with fully automatic loading systems, which, in principle, can eliminate the need for human presence in the sterile block except in emergency situations. However, it is difficult—perhaps impossible—to place temperature sensors in product vials when using an automatic loading system. Given the problems noted above with the routine use of product temperature sensors, it would seem reasonable to employ product temperature sensors only in development and validation, where vials near the center of an array could be monitored. With a robust process and suitable validation data, it may be assumed that production batches would run with the same product temperature history as the development and validation batches. Thus, product temperature would not be monitored during routine manufacturing. The simplest process design involves using a fixed shelf temperature:chamber pressure:time program.

Designing an *efficient* and *robust* process based upon a fixed shelf temperature:chamber pressure:time program is not a difficult assignment when the primary drying time is short. For example, if the primary drying time of an average batch is 6 h, designing for worst case of perhaps twice the primary drying time of an average batch would extend the average process time by only 6 h; however, if the primary drying time of an average batch is 4 days, designing for worst case will result in a significant reduction of production capacity. By using methodology

for remote sensing of the end point of primary drying (43), which will be discussed later, this process inefficiency can be virtually eliminated. Moreover, it is both possible and practical to monitor product temperature without placing temperature sensors in the product vials (48). This methodology, called manometric temperature measurement, is based on an analysis of the rate of pressure increase in the chamber when the valve separating the drying chamber from the condenser chamber is periodically quickly closed (and the pressure control system is deactivated) for a brief period of time (≈ 15 s). When the drying chamber is thus isolated from the condenser chamber, the chamber pressure increases due to four effects (Fig. 6): 1) sublimation at the ice–vapor interface at constant product temperature and transfer of water vapor through the dried cake; 2) dissipation of the temperature gradient in the frozen layer, thereby increasing the temperature at the ice–vapor interface; 3) heat flow from the shelf to the product, thereby increasing the temperature at the ice–vapor interface; and 4) natural air leaks from the surroundings into the chamber. The pressure rise data is fitted to a theoretical function to obtain the average product temperature at the ice–vapor interface. Effects 3 and 4 above both produce a linear increase in pressure with time whereas the other two effects are nonlinear. Effect 1 is dominant (Fig. 6), but a consideration of the other effects is necessary to obtain accurate product temperatures (48). Manometric temperature measurement gives

the temperature at the ice–vapor interface, which is the temperature relevant to collapse, and most important, gives a representative temperature of the product vials without risk of sterility compromise. The freeze dryer, however, must be computer-controlled so that product temperature data can be obtained in real time via mathematical analysis of the pressure rise data. Manometric temperature measurement can also be used to sense the endpoint of primary drying as well as providing accurate dried layer resistance data (48).

Process control and chamber pressure

Pressure control may be accomplished by one of three methods: controlled nitrogen leak, conductance control, or condenser temperature control. Pressure control by “controlled nitrogen leak” is accomplished by opening/closing a needle valve connected to a nitrogen source at atmospheric pressure in response to the deviation of the measured chamber pressure from the set point. Very fine pressure control, within ± 5 mTorr, can easily be achieved. Typically, sterile nitrogen is leaked into the drying chamber, but equally fine pressure control is achieved by leaking nitrogen into the vacuum line near the vacuum pumps. Although, to my knowledge, no relevant data exists, current dogma suggests that leaking into the drying chamber is preferred because the risk of sterility compromise is less. Conductance control is based upon modulating the resistance of the chamber to condenser pathway by partially closing/opening the valve separating the drying chamber from the condenser chamber (49). One disadvantage of this technique is the inability to control pressure during secondary drying. Once evolution of water vapor slows to very low rates (during secondary drying), the chamber pressure will reduce to whatever ultimate vacuum the system will produce that day. Although control of chamber pressure to regulate heat input is only necessary in primary drying, one could argue that a process that does not control pressure throughout the process is not fully reproducible. In general, this argument is without scientific foundation, but there are special circumstances where product contamination by adsorption of volatile stopper impurities (or other foreign vapors in the freeze dryer) may occur, and such contamination is more serious at very low chamber pressures (50). Here, one would want to control chamber pressure in secondary drying at a somewhat elevated level (≈ 200 mTorr). Chamber pressure can also be controlled by control of condenser temperature, provided the freeze dryer design provides for fine control of condenser temperature (49). Control of condenser temperature controls the vapor pressure of ice on the condenser, thereby controlling the partial pressure of water in the drying chamber. Due to

Fig. 6 Calculated contributions to the pressure rise in a manometric temperature measurement experiment. Calculations were made for a typical product with an initial ice temperature of -20°C , corresponding to an initial vapor pressure of 775 mTorr. Open circles = effect 1, sublimation; open triangles = effect 2, dissipation of temperature gradient; open squares = effect 3, heat flow from shelf to product; filled circles = sum of all effects. (Adapted from Ref. 48.)

natural air leaks and the finite pressure difference between condenser and chamber required for mass transfer, the controlled chamber pressure will be somewhat higher than the vapor pressure of ice on the condenser, perhaps 20–50 mTorr higher. Thus, to control chamber pressure at 200 mTorr, the condenser temperature would be controlled at a temperature around -35°C . With this mode of pressure control, the vapor in the drying chamber remains essentially 100% water vapor throughout the process, including secondary drying. Conversely, with pressure control by a nitrogen leak, the vapor changes from essentially 100% water vapor in primary drying to mostly nitrogen during secondary drying (Fig. 7). Thus, a process run with a nitrogen leak to provide pressure control is not necessarily the same as the corresponding process run with pressure control via control of condenser temperature. In general, the difference is not expected to be of practical significance. With a final product temperature of 25°C or greater in secondary drying, a chamber pressure of 200 mTorr pure water vapor produces a relative humidity of less than 0.8%, which is not high enough to impede secondary drying of most materials. However, chamber pressure control via condenser temperature control will not produce the change in gas composition noted in Fig. 7,

Fig. 7 Typical variation in gas composition in the drying chamber during secondary drying. Open circles: experimental values determined in a laboratory freeze dryer; filled triangles: theoretical values calculated from mass transfer theory and freeze dryer characteristics. (M.J. Pikal, Eli Lilly & Co., unpublished results.)

as the system passes from primary drying to secondary drying, which does limit the process control options for determining the end point of primary drying.

Process control: Effect of condenser performance

Depending upon dryer design and operating conditions, the condenser temperature may vary over a wide range. As long as the condenser temperature remains sufficiently low to allow control of the chamber pressure at the desired set point, the temperature of the condenser has no impact on the freeze-drying process (i.e., no change in any of the variables in Eq. 1). For example, if the chamber pressure is being controlled (via a nitrogen leak) at the target pressure of 0.10 Torr with a condenser temperature of -50°C , reduction of the condenser temperature to -70°C will have no effect on the process. Here, the reduced partial pressure of water at the condenser will be compensated by an increased partial pressure of nitrogen arising from an (automatic) increase in nitrogen leak rate. Although a detailed analysis of condenser performance is complex (49) and beyond the scope of this chapter, it should be noted that under conditions of very high sublimation rate, the condenser system may be overloaded, resulting in loss of pressure control (i.e., the chamber pressure increases beyond control). Unless the shelf temperature is sharply decreased, a “run-away” condition may develop with loss of product temperature control and ultimately, loss of the batch due to product collapse or ice melt. An overloaded condenser may reflect uneven ice build-up at the condenser plates caused by suboptimal design or operation, but may also arise from operation beyond the design capability of the refrigeration system (49). That is, the refrigeration system may not be able to remove heat from rapidly condensing water vapor (i.e., from very high sublimation rate) and yet maintain the condenser plate temperature low.

Process control: Determination of the end point of primary drying

Typically the shelf temperature setting used in primary drying is much lower than the shelf temperature required for efficient removal of residual water during secondary drying. Because an increase in shelf temperature before all vials have completed primary drying carries a high risk of product collapse, some indicator of the end of primary drying is needed for optimum process control. Of course, one can increase the temperature for secondary drying at a fixed time, but as discussed earlier, such a process is not an optimum one (i.e., the process is normally longer than necessary). Product temperature response is the most common indicator of the end of primary drying. Here, the time is noted when all product temperature sensors

approach the shelf temperature being used in primary drying. Next, a delay time or soak period is introduced to compensate for the fact that the vials containing temperature sensors are not typical of the batch as a whole. After this delay time, the shelf temperature is increased from the primary drying setting to the setting used for secondary drying. As determination of the appropriate delay time is difficult, the delay times used are often quite arbitrary. The principle problem is that freezing bias normally differs considerably between development and manufacturing. Thus, the optimum delay time for manufacturing cannot be determined in most development laboratories. It is obvious that use of product temperature sensors to determine the end point of primary drying is not entirely satisfactory. As suggested earlier, manometric temperature measurement may be used to determine the end point of primary drying. A far simpler method is to base the determination of the end point upon a real time measurement of the vapor composition in the freeze dryer chamber. As primary drying ends, and the process passes into secondary drying, the composition of the vapor in the drying chamber shifts from nearly pure water vapor to nearly pure nitrogen (Fig. 7), assuming chamber pressure is being controlled via a nitrogen gas leak. A sensitive and inexpensive measurement of vapor composition is provided by an electronic moisture sensor with output in dew point or partial pressure of water (43, 51). An electronic moisture sensor has the sensitivity to determine presence of residual ice in less than 1% of the vials (43), and under some conditions can also be employed to determine the end point of secondary drying—i.e., when the residual moisture has been reduced to below the target levels (51).

Secondary Drying: Desorption of Water from the Freeze Concentrate

Product temperature control and glass transitions

The concept that one must maintain the product temperature below the collapse temperature during primary drying is now well accepted. Exceeding the collapse temperature will cause loss of product elegance, which will vary from moderate deformation and shrinkage to a complete melt and deposition along the walls and bottom of the vial. Structural collapse also may occur during secondary drying or during storage of the dried product, particularly if the dried product contains high levels of residual moisture, and the storage temperature is high. If the product temperature exceeds its glass transition temperature, cake shrinkage and deformation will occur. Such an event is a less common problem during secondary

Fig. 8 Variation of glass transition temperature and product temperature for moxalactam di-sodium during secondary drying. (Calculated from data in Refs. 25 and 40.)

drying than is collapse during primary drying, largely because most secondary drying processes are extremely conservative during the early stage where a glass transition is most likely. As the water content of the amorphous phase decreases during drying, the glass transition temperature increases very sharply. Some representative data are shown in Fig. 8. If the shelf temperature remains at the setting used in primary drying for the first few hours of secondary drying, as is common practice, the glass transition temperature will nearly always rise much faster than will the product temperature. However, if one were to optimize secondary drying, and therefore, eliminate most of the dead time in early secondary drying, the potential for a glass transition would increase dramatically. Here, a knowledge of the glass transition temperature as a function of water content would be required for process optimization.

Optimum residual moisture

The optimum residual moisture for a given product must be established by empirical studies. Certainly, to eliminate the possibility of a structural collapse during storage, the water content needs to be low enough so that the glass-transition temperature is well above the highest temperature relevant to product distribution and storage. Moreover, in our experience with both small molecules and proteins, in-process degradation is generally relatively insensitive to the final moisture content, and storage stability normally improves as residual moisture decreases, although the relationship between stability and residual water is not

Fig. 9 The effect of residual water on the stability of freeze-dried proteins. Circles = human growth hormone deamidation and oxidation at 25°C, %/month (From Ref. 19); squares = aggregation of human serum albumin at 50°C, %/day (Ref. 52); triangles = hemoglobin oxidation at 23°C in a sucrose formulation, %/year (Ref. 53).

necessarily linear. Data for human growth hormone (hGH) formulated with glycine and mannitol (19), human serum albumin (52), and hemoglobin formulated with sucrose (53) illustrate the range of behavior normally encountered (Fig. 9). The rate of chemical degradation of hGH at 25°C (methionine oxidation and asparagine deamidation) increases in highly nonlinear fashion by nearly an order of magnitude as the moisture content varies from 1% to 2.5% (19); the rate of aggregation of human serum albumin increases linearly with increasing moisture content (52); and the rate of hemoglobin oxidation at room temperature doubles as the residual water content increases from 1% to 4% (53). Although the optimum moisture content for storage stability may be zero, the gain in stability between about 1% water and zero water content is often not sufficient to justify the additional processing complications in achieving and maintaining extremely low water contents. An exception is storage stability of a monoclonal antibody–vinca alkaloid conjugate formulation where stability is sensitive to very low levels of residual moisture (22).

The decrease in storage stability accompanied by an increase in residual moisture is often interpreted in terms of molecular mobility in the solid. That is, higher water content facilitates the mobility needed to support reactivity of the protein. One interpretation states that above monolayer levels of water, the protein has increased

conformational flexibility, and the additional water has the ability to mobilize water and other potential reactants in the amorphous protein phase (54). Both effects are expected to increase the rate of protein degradation. Alternatively, water plasticizes the amorphous phase, thereby lowering the glass transition temperature, T_g . Indeed, if sufficient water is present to lower T_g below the storage temperature, the amorphous phase would be in a fluid state, with greater mobility and greater reactivity than when stored below T_g in a glassy solid state. A system stored above its T_g would also suffer cake collapse and loss of pharmaceutical elegance. Although the monolayer and the glass transition interpretations are similar in that they both attribute the increased reactivity to water induced mobility in the amorphous phase, they differ in that a system above the monolayer level of water is not necessarily above the glass-transition temperature. Furthermore, as the level of water equivalent to monolayer coverage is essentially independent of temperature, the monolayer concept predicts that the trend in stability with water content is independent of temperature. For example, if monolayer coverage is equivalent to 10% water, protein reactivity would increase sharply above 10% water at all temperatures. Conversely, the glass transition interpretation states that the key stability variable is the difference between the glass transition temperature and the storage temperature, $T - T_g$. Here, reactivity increases sharply when $T > T_g$, so the sudden onset of reactivity depends on both T and the water content through the effect of water content on T_g .

Although most empirical and theoretical evidence suggest that storage stability improves monotonically as the water content decreases, we must also acknowledge the common assumption that there is a critical nonzero level of water that a protein requires for conformational stability in the freeze-dried solid, and therefore, some intermediate level of residual water would be optimum for stability. Although direct experimental evidence for this assumption is meager, some systems do have inferior stability when highly desiccated. Influenza virus is clearly less stable when the residual moisture deviates from the optimum 1.7% (55), but the direct relevance of this observation to protein formulations is uncertain. Aggregation of excipient-free tissue plasminogen activator at high temperature is faster at low water content (56), and aggregation of excipient-free hGH during storage at 25°C is faster in samples that, at some time in their history, have been highly desiccated (19).

Factors impacting drying rate

Water removal during secondary drying involves diffusion of water in the glassy solid, evaporation at the solid–vapor

Fig. 10 Examples of the kinetics of secondary drying. Triangles = mannitol (crystalline); squares = poly (vinylpyrrolidone); circles = moxalactam di-sodium (amorphous). All solids were prepared by freeze-drying a 5% aqueous solution from a 1-cm fill depth, followed by hydration to a uniform moisture level of $\approx 7\%$. The quantity, F , is the fractional attainment of equilibrium, which corresponds to near zero water content. The secondary drying conditions were: product temperature = 18°C ; chamber pressure = 200 mTorr. (From Ref. 40.)

boundary, and flow through the pore structure of the dried cake. During the early portion of secondary drying, water content is high, and the drying rate is high in spite of the relatively low temperature of the solid (40). An illustration of secondary drying kinetics under isothermal conditions is given in Fig. 10 (40) for samples initially about 7% water. Mannitol is crystalline whereas povidone and moxalactam are 100% amorphous. Even at the start of the experiment, the glass transition temperatures of povidone and moxalactam are well above the sample temperature of 18°C . Thus, water is being removed from either an essentially crystalline solid (mannitol) or glassy amorphous solids (povidone and moxalactam). The symbol F represents the fractional attainment of equilibrium, which in these experiments is near zero water content. Thus, $1-F$ represents a normalized water content with a value of unity representing no progress in drying. Although the quantitative aspects of drying behavior are obviously specific to the product, in each case, the water content is reduced sharply during the first 1–2 h, followed by a period of much lower drying rate. If the drying rate were directly proportional to the residual water content, drying kinetics would be first order, and the curves in Fig. 10 would be straight lines. A simple diffusion model based upon constant diffusion constant and constant area

for diffusion would also predict linear semilog drying curves (40). Obviously, the curves are not straight lines. The residual water content appears to approach a plateau level, which is specific to the product. For the mannitol data, the plateau level of residual water is very low (≈ 0.1 – 0.2%) and probably represents occluded water in the crystalline mannitol. For the amorphous samples, povidone and moxalactam, the plateau levels are quite high, $\approx 1\%$ for povidone and $\approx 3\%$ for moxalactam (i.e., a significant fraction of the water appears to be bound). However, calculations based upon equilibrium water desorption isotherms and the measured partial pressures of water in the drying chamber demonstrate that the residual water present at the end of 6 h is far above the equilibrium water content (40). Thus, the residual water is *not* bound in a thermodynamic sense, but rather is kinetically trapped, a result, at least in part, of decreasing effective surface area for desorption of water as the smaller more rapidly drying solid particles are dried (40). For a given product, the plateau level of water decreases as the drying temperature is increased, decreases as the specific surface area of the solid increases, but is relatively insensitive to the thickness of the dried cake (40).

Traditional freeze-drying practice has often used very low chamber pressures during secondary drying, presumably in the belief that the rate of secondary drying would be accelerated by the use of the low pressures. However, it is found (40) that the rate of secondary drying is insensitive to chamber pressure, at least with pressures in the range of 0–0.2 Torr (40). This empirical observation is consistent with the conclusion that the rate-limiting mass transfer process for drying an amorphous solid is either diffusion in the solid or evaporation at the solid–vapor boundary, probably the latter (40). As the use of very low pressures in secondary drying may facilitate contamination of the product by adsorption of impurity gases from the stopper or other sources (50), it is clear that relatively high chamber pressures (≈ 0.1 – 0.2 Torr) should generally be used for secondary drying. Of course, extremely high chamber pressures (≈ 1 Torr) should perhaps be avoided. With very high chamber pressures, flow of water vapor through the pore structure would become rate limiting, and the very high pressure would then decrease the rate of drying.

Changes in moisture content during storage

Often one employs a heroic secondary drying process to reduce the residual water content to very low levels only to find that the moisture content increases during storage. Although moisture transfer from ambient through the stopper is possible, the increase in moisture content is most

Fig. 11 Kinetics of water transfer from stoppers to 25 mg freeze dried lactose. The stoppers were 13 mm finish West 1816 gray butyl stoppers that were steam sterilized and vacuum dried for 1 hour. Circles = 40°C; triangles = 25°C; squares = 5°C. (From Ref. 57.)

often related to moisture release by the stopper (57). This phenomenon is illustrated in Fig. 11, where the time dependence of moisture content in 25 mg of freeze-dried lactose is given. Here, the stoppers were gray butyl stoppers that had been previously steam sterilized, followed by 1 h of vacuum drying to remove excess water. The symbols represent experimental data for 40°C, 25°C, and 5°C storage, and the smooth curves represent the best fit to a theoretical model (57). It should be noted that at least at 40°C and 25°C storage, the moisture content increases sharply from 1%, but then reaches a plateau value of about 4.3%, suggesting that equilibrium has been reached. That is, at the plateau value of 4.3% water, the activity of the water in the stopper is equal to the activity of water in the lactose and mass transfer ceases. In other studies, we have noted samples deliberately prepared to be initially of high water content have lost water during storage. In short, there is moisture equilibration between moisture in the stopper and moisture in the product that may either increase the moisture content of a dry product or decrease the moisture content of a wet product. The plateau or equilibrium level of water appears to be independent of temperature. The equilibrium values for 40°C storage and 25°C storage are identical, and the moisture content values for 5°C storage appear to be approaching the same equilibrium value of 4.3%. The rate of approach to equilibrium, however, is strongly temperature dependent. The equilibrium level of water is

strongly dependent upon the stopper treatment history. Stoppers vacuum dried for 8 h after steam sterilization allowed only a small increase in moisture content during storage. The equilibrium water content is lower for a higher mass of solid, and is slightly higher for a more hygroscopic product (57).

The moisture exchange between stopper and product may have important stability consequences. Absorption of moisture from the stopper may result in a product which has, after time, a moisture content high enough so that the glass transition temperature is below the storage temperature. Structural collapse will result, and stability of the product may well be compromised. Moreover, because the glass transition temperature often changes dramatically in a narrow range of water content, the onset of instability could be quite sudden. Moisture exchange may be moderated by extensive high temperature vacuum drying of the stoppers after steam sterilization. A better solution is to employ alternate rubber formulations that are less prone to release water to the product. Such stopper formulations are now available from several vendors.

FORMULATION AND STABILITY

Function of Excipients

Most freeze-dried products contain several components in addition to the drug or active component. These additional components, called excipients, are intended to serve a specific function, normally related to stability or process, and may constitute the major fraction of the freeze-dried solid.

With some products, the quantity of drug per vial is extremely small. Here, bulking agents such as mannitol or glycine are used to provide product elegance (i.e., satisfactory appearance) as well as to provide sufficient cake mechanical strength to avoid product blow-out. When a very dilute solution is freeze dried, the flow of water vapor during primary drying may generate sufficient force on the fragile cake to break the cake structure and carry some of the product out of the vial with the water vapor stream. Product blow-out normally occurs only when the solution to be freeze dried is very low in total solids (1% or less). Thus, with low dose drugs, a bulking agent may be a critical formulation component.

Collapse temperature modifiers are excipients that will increase the collapse temperature to allow more efficient freeze-drying without collapse. Such materials may also function as bulking agents and/or stabilizers. Dextran ($T_c = -10^\circ\text{C}$), hydroxyethyl starch ($T_c = -10^\circ\text{C}$), ficoll ($T_c = -20^\circ\text{C}$), gelatin ($T_c = -8^\circ\text{C}$) are examples.

Although none of these materials are commonly used in parenteral formulations, dextran and hydroxyethyl starch are used in large quantities as IV therapeutic agents, and therefore, would presumably be acceptable as excipients. Usually, the collapse temperature of a mixture is intermediate between the collapse temperatures of the individual components (58), but collapse temperatures of candidate formulations cannot be predicted with high accuracy.

Macroscopic collapse may often be avoided by use of a crystalline matrix component. Here a readily crystallizable component is added at a relatively high level (i.e., more than 50% of total solids and ideally much more) such that a crystalline matrix is formed. Freeze drying such a formulation amounts to freeze-drying with microscopic or partial collapse (i.e., complete collapse of the amorphous phase), but cake structure is maintained by the crystalline component. Thus, both elegance and good reconstitution time will be maintained, and the samples will normally dry to low residual water with ease. However, if collapse of the amorphous phase containing the protein leads to degradation, this method for circumventing collapse is not viable. Glycine and mannitol are commonly used as crystalline matrix components. This excipient function is, in reality, a special case of the use of a bulking agent.

Particularly with proteins, excipients are often added to prevent degradation, as for example, lyoprotectants, antioxidants, nonionic surfactants, metal ion chelators, and other proteins such as BSA in diagnostic products. In many cases, the stabilizer may also serve as a bulking agent. Glycine, mannitol, sucrose, and lactose are perhaps the most commonly used stabilizers. However, as lactose is a reducing sugar and commonly reacts with proteins, its use must be questioned. Both mannitol and glycine tend to crystallize, and are, therefore, generally poor choices as stabilizers when used alone. Sugars, in particular sucrose, are often effective lyoprotectants, as well as enhancers of storage stability.

Buffers are often added to control pH, but caution must be exercised when buffers are used in a formulation to be freeze dried. As discussed earlier, crystallization of either buffer component (acid or base) during freezing may cause a significant pH shift during freezing, thereby causing greater pH variation than would have been obtained in an unbuffered system.

Products intended for human use are occasionally formulated with NaCl or glycerol to make the reconstituted product isotonic. This practice is normally not a requirement for IV drugs, but can be quite important in minimizing pain on injection of subcutaneous and IM doses. In general, and in particular with proteins, isotonic

adjustment is best accomplished by including the tonicity modifier in the diluent rather than in the freeze-dried product. Sodium chloride and glycerol can lower the collapse temperature significantly, and sodium chloride may cause aggregation of the protein during freeze drying.

With multidose products, there is a need for use of a preservative to prevent microbial growth during the period of product use. Mixtures of ethyl- and methyl-parabens are a common choice as are phenol and *m*-Cresol. As preservatives are used at extremely low levels (i.e., $\leq 0.1\%$ w/w in solution), they normally would not alter the collapse characteristics of the formulation. However, since the preservative is not needed during the freeze-drying process, to keep the formulation for freeze-drying as simple as possible, preservatives are best introduced via the diluent intended for reconstitution.

Surfactants may be added at low levels (i.e., $\approx 0.05\%$ w/w in solution) for several purposes. Surfactants may aid reconstitution if the drug does wet well, and surfactants are often added to low dose products to minimize losses due to surface adsorption. Surfactants may also be effective as stabilizers in low dose protein systems.

Relationships Between Formulation and Process

Particularly for freeze-dried products, formulation and process are interrelated. Properties of the formulation, in particular the collapse temperature, will have a significant impact on the ease of processing. An efficient process is one that runs at a high product temperature. However, the temperature cannot be too high or product quality will be compromised. As the glass transition temperature depends on chemical composition of the amorphous phase, T_g' and collapse temperature are strongly formulation dependent. Collapse temperatures for common excipient systems vary from less than -50°C to around -10°C (Table 2).

The collapse temperature depends upon the composition of the amorphous phase, and crystallization of one or more components may significantly alter the collapse temperature. In this way, process variations that induce crystallization may alter the physical state of the formulation. For example, human growth hormone (hGH) formulated with glycine and mannitol in a hGH:glycine:mannitol weight ratio of 1:1:5 may form a completely amorphous system if frozen very quickly. Here, the collapse temperature is -24°C . However, a slower freeze allows crystallization of most of the mannitol, resulting in a collapse temperature greater than -5°C (18). Another example is provided by the glycine:sucrose system (64–68) where glycine is present in excess of the sucrose. If frozen quickly, glycine remains

^aCollapse temperature data were obtained with freeze-drying microscopy and T_g' data were obtained by DSC at roughly 10°C/min heating rates and represent mid-points of the glass transition region. Molecular weight is given for polymers when the data are sensitive to molecular weight. When significant differences exist between laboratories, both values are given. Values in parenthesis were estimated by extrapolation from noncrystallizing mixtures to the pure compound.

amorphous, and the glycine:sucrose freeze concentrate has a very low collapse temperature (i.e., roughly -45°C, depending upon the exact composition). However, if glycine is allowed to crystallize, the glass-transition temperature is essentially that of a sucrose freeze concentrate (i.e., about -34°C). Further, as the structure is maintained by the crystalline glycine, exceeding T_g' does not result in macroscopic collapse, and the system may be freeze dried without apparent collapse even at temperatures exceeding -15°C. Thus, crystallization can transform a formulation from one that is nearly

impossible to freeze dry in a commercial operation to one where freeze-drying is relatively easy. Clearly, if both glycine and sucrose are included in the formulation, the level of glycine must be either very low or very high relative to sucrose. If the level of glycine in the sucrose phase is very low, glycine will not crystallize but the impact on T_g' will be minimal. If the level of glycine is high, glycine can be induced to crystallize nearly completely (66, 68), thereby minimizing the level of glycine in the amorphous phase and maximizing the T_g' of the formulation.

The glass-transition temperature of a multicomponent amorphous system may be estimated from glass transition temperatures of the individual amorphous components (69). The simplest expression, commonly referred to as the Fox equation, is

$$\frac{1}{T_g} = \frac{w_1}{T_{g1}} + \frac{w_2}{T_{g2}} \quad (2)$$

where w_i is the weight fraction of component i and T_{gi} is the glass transition temperature of pure component i . Generalization of Eq. 2 to systems of more than two components is obvious. The effect of a second solute component on a formulation may be roughly calculated from Eq. 1 if T_{gi} in Eq. 2 is identified with T_g' of aqueous component i , and w_i are weight fractions of solute relative to the total mass of solute. Although Eq. 2 does not strictly apply to a freeze concentrate containing two (or more) solute components and water, such calculations from T_g' data are sufficiently accurate to be of practical use. For example, the effect of glycine on T_g' of aqueous sucrose systems (65) is fully consistent with Eq. 2.

Bulking Agents

General considerations

Bulking agents are intended to be inert and simply function as fillers to increase the density of the product cake. Product elegance is improved and product blow-out is prevented, but the bulking agent is not intended to provide enhanced chemical or physical stability of the drug substance. Amorphous excipients can function as bulking agents, but most amorphous excipients have relatively low collapse temperatures and therefore require low drying temperatures and long processing times. For example, although lactose has been used as a bulking agent, the relatively low collapse temperature (-31°C) requires long processing times. In addition, lactose is a reducing sugar and will chemically react with amine functionality, and therefore, cannot be used with many drugs. Although not in common use as a freeze-drying excipient, hydroxyethylstarch is an example of an inert amorphous additive with a high collapse temperature and therefore, could function as a bulking agent without requiring long processing times. However, hydroxyethylstarch tends to undergo some cake shrinkage and cracking during drying and therefore, provides a less elegant product than do the common crystalline bulking agents, glycine and mannitol. Since sorbitol is simply an isomer of mannitol, one might expect sorbitol could serve as a bulking agent. However, sorbitol does not easily crystallize during freeze-drying, and amorphous sorbitol has a

collapse temperature around -45°C (Table 2), thereby preventing its use at high levels in formulations for freeze-drying. Human serum albumin (HSA) or in diagnostic products, bovine serum albumin (BSA), have seen use as bulking agents and/or stabilizers. However, given current concerns regarding excipients isolated from human sources, use of HSA in new pharmaceutical products should be questioned. Mannitol is by far the most commonly used bulking agent. A mannitol-based formulation is elegant, reconstitutes quickly, and except for the potential of vial breakage (26, 70, 71), is generally easy to freeze dry without risk of product defects. Vial breakage is minimized by small fill depths, lower mannitol concentration, slow freezing, and avoiding freezing temperatures less than about -25°C until crystallization is complete. Glycine functions well as a bulking agent. Glycine crystallizes easily to form an elegant product that reconstitutes quickly and does not induce vial breakage. However, a glycine cake is more fragile than a mannitol cake, and is generally perceived as being somewhat less elegant than a mannitol cake.

Polymorphism in crystalline bulking agents

In general, the polymorphism issue of greatest significance in freeze-drying is whether or not a given component is crystalline or amorphous. Which crystalline polymorph forms is usually of secondary importance. However, it should be noted that both mannitol and glycine do exhibit crystalline polymorphism in freeze-dried systems (72–75). The only crystal polymorphism issue of known significance is the formation of a hydrate of mannitol (73, 75). Under some conditions, not fully understood, mannitol forms a hydrate that does not easily desolvate to an anhydrate during secondary drying. Secondary drying at temperatures in excess of 50°C appear to be necessary to desolvate the hydrate. Thus, samples of freeze-dried mannitol may have high residual water content if secondary drying temperatures were moderate. If this residual water were to remain bound in the hydrate crystal lattice, the high residual water content would simply be a curiosity. However, during storage, particularly at elevated temperature, the hydrate slowly desolvates, thereby releasing water to the amorphous drug phase. Such a scenario may compromise storage stability, particularly during accelerated stability tests.

Conditions for crystallization of bulking agents

A number of factors are critical for crystallization of the bulking agent. First, the nature of the bulking agent is of obvious importance. Unless the bulking agent will readily crystallize from an aqueous system at ambient temperatures, crystallization during freezing is unlikely. Although

both mannitol and glycine do readily crystallize during freezing, there are many other solutes that readily crystallize and are at least potentially acceptable as excipients for parenteral drugs. Mannitol and glycine are simply the most commonly used bulking agents. Crystallization is favored by higher concentrations of crystallizable solute, and perhaps most important, the bulking agent must be the major solute component to obtain reliable crystallization. The presence of high levels of other solutes, particularly those that remain amorphous, will generally impede or prevent crystallization of the bulking agent. As a general formulation rule, one should employ the crystallizable bulking agent at a concentration (weight percent) that is at least a factor of three greater than the sum of the concentrations of all other solute components. In addition, because resistance of the dry layer to flux of water vapor increases as the concentration of total solids increases, thereby prolonging primary drying, one should avoid total solids concentrations much above 100 mg/ml when possible. A rigid adherence to both of these rules would suggest that one would not employ a bulking agent if the drug concentration were much in excess of 25 mg/ml. Indeed, because a bulking agent is normally not needed to avoid product blow-out at drug concentrations above 25 mg/ml, one should question the use of bulking agents in such applications.

Surfactants

Generally, surfactants are employed to reduce surface adsorption losses of low-dose drugs, to improve wetting and reconstitution behavior, and to stabilize proteins during freezing. In nearly all applications, it is a nonionic surfactant that is used, and by far the most commonly used surfactant is polysorbate 80. However, it should be noted that the popularity of polysorbate 80 is due more to its extensive history of use and presumed greater acceptance by regulatory agencies than to its demonstrated superior performance in a given application. In practice, the surfactant level is very low, typically 0.01–0.1% w/v.

Proteins and surface active drugs often adsorb on filters, solution-processing equipment, and container surfaces, thereby producing loss of drug. Such losses are normally only of practical significance if the drug concentration is very low (i.e., when the total amount of drug loss is a significant percentage of the drug in solution). Addition of a low concentration of surfactant will frequently reduce the level of drug adsorption simply because the surfactant is preferentially adsorbed at the surfaces. With proteins, surface-adsorption effects may be considerably more

complex and damaging. Many proteins adsorb at interfaces, particularly the air–water interface, suffer a conformational change, desorb from the interface, and either refold or combine with other conformationally altered molecules, thereby leading to irreversible aggregation.

Human growth hormone aggregates extensively during shaking an aqueous solution, but this aggregation can be nearly eliminated by adding Polysorbate 20 to the formulation (76). It should be noted that although other surfactants (including polysorbate 80) were studied, Polysorbate 20 was the most effective stabilizer. In this study, all surfactant levels studied were above the surfactant critical micelle concentration (CMC), but the rate of aggregation decreases linearly as a function of increasing polysorbate 20:hGH mole ratio until it exceeds 2.0. This linearity provides a clue to the stabilization mechanism. As surfactant adsorption to the air–water interface would be expected to depend on the surfactant monomer concentration, and the monomer concentration is constant above the CMC, a stabilization mechanism involving adsorption of surfactant to the air–water interface would be expected to produce a roughly constant stabilization effect at all surfactant concentrations above the CMC. The data are not consistent with this prediction. However, it is known that polysorbate 20 binds to hGH with a stoichiometry of about 2.5 to 4 (77). Thus, it seems plausible that stabilization during shaking involves binding of surfactant to the surface of the protein (77).

Aggregation of hemoglobin during freeze–thaw is essentially eliminated by addition of polysorbate 80 at concentrations from 0.0125% to 0.1% (78). Without polysorbate 80, particle formation after five freeze–thaw cycles increased by more than an order of magnitude when freezing to -20°C and by about a factor of five when freezing to -80°C . However, use of polysorbate 80 reduced particulate generation at both freezing temperatures to a level where particulate levels after freeze–thaw were not significantly different than before freezing. Attempts to demonstrate binding of the surfactant to hemoglobin were unsuccessful, suggesting that the stabilization mechanism does not involve binding to the protein. Rather, it was proposed that stabilization involves surfactant adsorption at the interface, thereby preventing the protein from adsorbing at interfaces.

Although one cannot always expect protein aggregation to be eliminated as effectively by addition of surfactant as demonstrated in the above examples, it is certainly prudent to test the effect of surfactants in situations where protein aggregation is a problem during freeze–thaw or during solution handling.

Stabilizers

Types of stabilizers

A stabilizer is simply a formulation component without physiological effect that is added to the formulation to maintain the physical or chemical stability of the drug substance. As discussed in the previous section, the function of a surfactant may be to stabilize, and as control of pH is often critical to stability, one might consider buffers to be stabilizers. However, in this section we will address stabilizers other than surfactants or buffers. Further, as most of the stabilization literature deals with proteins, our discussion will focus on proteins, although in principle many stabilization principles apply to small molecules as well.

Minimizing oxidation

Although oxidation is a very common degradation pathway in pharmaceutical systems, one might expect that oxidation problems in freeze-dried products would be easily solved by elimination of oxygen from the system during processing; that is, because the product is dried in a vacuum environment and the vials either sealed in vacuum or in an atmosphere of an inert gas (i.e., nitrogen), no oxygen will be present to support an oxidation reaction. Indeed, storage stability of human growth hormone is greatly improved in vials back-filled with nitrogen compared to vials back-filled with oxygen (19). However, significant oxidation was also observed in samples back-filled with nitrogen. In practice, complete elimination of oxygen from the solution being processed is unlikely, and some oxygen may well be trapped in the amorphous solute phase after freezing and not be completely removed during drying. Further, due to a variety of causes including diffusion from the atmosphere over time, oxygen content in the vial headspace may easily reach levels of about 1%. Even 1% oxygen in the vial headspace is sufficient, from a stoichiometric viewpoint, to produce substantial decomposition, particularly with high-molecular-weight drugs. For example, with a 5-mg dose of human growth hormone ($M = 22.5$ kD) in a 5-cc vial, 1% oxygen in the headspace represents a factor of ten excess of the oxygen required for complete oxidation of the protein.

As ground-state molecular oxygen is not particularly reactive, presence of oxygen is not the only requirement for a rapid oxidation reaction. Activation of molecular oxygen to more reactive species requires light (i.e., photoactivation to singlet oxygen, $^1\text{O}_2$), or presence of a reducing agent and trace levels of transition metal ions (i.e., iron and/or copper), which can then convert molecular oxygen into more reactive oxidizing agents

such as superoxide radical ($\text{O}_2^{\cdot-}$), hydroxyl radical ($\cdot\text{OH}$), or hydrogen peroxide (H_2O_2) (79). Transition metal ions are often present in excipients, and processing in stainless steel equipment can lead to significant iron contamination. As the role of the transition metal ion is catalytic, only trace levels are required. The reducing agent is consumed in the conversion of molecular oxygen into reactive oxygen species, so higher levels of reducing agent are required for significant degradation of a drug. However, higher levels could still represent contamination from impurities in the drug and/or excipients. In the example of 5 mg hGH, a low-molecular-weight reducing agent ($M \approx 100$) present at a level of 0.1% w/w of the amount of hGH could lead to oxidation of more than 10% of the protein. The reducing agent could also originate from a misguided attempt to suppress oxidation by addition of an antioxidant such as ascorbate. Ascorbate may function as an antioxidant in some circumstances but will also function as an effective prooxidant and reduce molecular oxygen to reactive oxygen species in the presence of transition metal ions such as iron or copper (79, 80). Finally, peroxides are common contaminants in polyethylene glycols and nonionic surfactants and can serve as the oxidant. Thus, an attempt to stabilize protein conformation by addition of these materials may well chemically destabilize if oxidation is a possible degradation pathway.

A number of amino acid residues are subject to oxidation. Metal-catalyzed oxidation of methionine to methionine sulfoxide and other products is perhaps the most common pathway. Oxidation of cysteine to form either nonnative intra- or intermolecular disulfide bonds is also common, and histidine residues are also easily oxidized in metal-catalyzed pathways, with tryptophan and tyrosine being degraded by light-catalyzed oxidations (79). Mechanisms are complex, and even with a given reaction such as methionine oxidation, the active oxygen species and reaction product(s) varies with the experimental conditions (79, 80); thus, stabilization is difficult. Certainly, oxygen content in the solution being processed should be minimized, and the product should be sealed in the freeze dryer with either vacuum or nitrogen in the headspace. Due to the negative impact of even small amounts of transition metal ions, prooxidants, and peroxides, the bulk drug substance and excipients need to have rigid specifications. Formulation pH and the type of buffer salt may also be important (80). The optimum conditions vary with the application, and some empirical screening experiments are necessary to optimize a given formulation.

Specific chemical components may also be added in an attempt to retard oxidation. The classical solution, addition

of an antioxidant, must be approached with caution as the antioxidant may function as a prooxidant in a metal-catalyzed conversion of molecular oxygen into reactive oxygen species. Likewise, addition of a metal-complexing agent such as EDTA does not always retard oxidation. In fact, oxidation may be accelerated by complexing the transition metal (80). With most metal-catalyzed oxidations, the oxidation mechanism is a site-specific one, where the reduced form of the metal binds to a residue such as histidine on the protein and converts oxygen to reactive oxygen species at that site, which in turn oxidizes another residue nearby (81). In cases where complexation with EDTA facilitates oxidation, it is assumed that the EDTA-metal complex binds more strongly to the protein and is therefore more effective in generation of reactive oxygen species near a reactive residue (81). However, addition of EDTA does retard oxidation in some cases (82), and it would seem prudent to screen several complexing agents for impact on oxidation. Scavengers for reactive oxygen species, hydroxyl radical, $\cdot\text{OH}$, and singlet oxygen, $^1\text{O}_2$, may also retard oxidation (79, 83), but the results are highly specific to the system. For example, for iron-catalyzed oxidation of a methionine-containing peptide, thiourea was found effective for both ascorbate and dithiothreitol prooxidant systems but mannitol was effective only for the dithiothreitol prooxidant system (83).

Stabilization during freezing

In the context of proteins, stability has two distinct meanings. The term pharmaceutical stability refers to the ability of a protein to be processed, distributed, and used without irreversible change in primary structure, conformation, or state of aggregation. We refer to pharmaceutical instability as degradation. However, the phrase protein stability is also commonly used to describe the position of the equilibrium between native and unfolded conformations. If a protein formulation requires a high level of chemical denaturant, or a high temperature, to shift the equilibrium between native and unfolded in favor of the unfolded state, the protein is said to be stable. This meaning of stability I call "thermodynamic stability." Thermodynamic instability involves physical changes, somewhat analogous to a thermodynamic change of state. Pharmaceutical instability may be purely a result of a physical change (i.e., noncovalent aggregation), but may also involve changes in primary structure or, in other words, chemical degradation. Certainly, chemical transformations such as oxidation and deamidation are degradations as is aggregation to form insoluble precipitates.

Pharmaceutical stability and thermodynamic stability are not necessarily directly related. For example, a protein

may exhibit thermodynamic instability during freeze-drying and unfold, but if no irreversible reactions occur during storage or during reconstitution, the reconstituted protein may refold completely within seconds and, therefore, display perfect pharmaceutical stability. A protein that remains in the native state and is thermodynamically stable may still degrade via chemical reactions such as deamidation and oxidation over storage times of years, particularly if the reactive moiety is located on the protein surface. Conversely, thermodynamic instability may well be a prelude to degradation. Certainly, an unfolded protein could expose normally buried and protected methionine and asparagine residues to the solution environment and render these residues more reactive. Also, degradation via irreversible aggregation is believed to often proceed through unfolded or partially unfolded conformations as intermediates (84).

Many proteins survive the freeze-drying process with little or no degradation, whereas other proteins exhibit significant degradation and loss of activity during processing. Degradation during the freeze-drying process may arise during freezing and/or during drying, and it is useful to establish when in the process degradation occurs. As a measure of the degradation during freezing, freeze-thaw stability studies are carried out, and to estimate (roughly) the degradation during drying, stability during freeze-drying is compared to stability during freeze-thaw. The basic assumption is that degradation during thawing is comparable to degradation during reconstitution; therefore, the difference in activity between a freeze-dried-reconstituted sample and a freeze-thawed sample is a measure of the loss in activity during drying. This assumption is likely a reasonable approximation for a fast thawing process. One observation of particular significance is that some excipients stabilize during both freezing and drying (called lyoprotectants), whereas others stabilize only during freezing (called cryoprotectants) (41, 85, 86).

If degradation occurs only during freezing and practical variations in the freezing process do not eliminate the problem, it is obvious that a cryoprotectant system is required. However, as a number of distinct stresses may develop during freezing, the proper choice of cryoprotectant is not always obvious. Provided some information regarding the degradation pathway is available, the stabilization strategy could be quite specific. For example, if oxidation is suspected to be a major pathway, the recommendations regarding minimization of oxidation should be followed. If aggregation is a major problem, the use of nonionic surfactants should be considered, or if it is known that a change in pH caused by buffer crystallization is a problem, steps to minimize pH change during freezing

need to be taken. Use of an alternative buffer system or simply use of very low levels of the buffer might well eliminate the pH change and solve the stability problem. Alternatively, addition of an excipient (i.e., sucrose or trehalose) that will interfere with buffer crystallization will also prevent excessive pH shift during freezing (41, 85, 86).

In addition to the specific stabilization strategies noted, one may also employ a general stabilization strategy that is based upon addition of components that normally increase the thermodynamic stability of the protein. That is, addition of a component that will increase the free energy of denaturation will moderate the effect of various freezing stresses that cause a decrease in the free energy of denaturation, with the net result that even during freezing, the native conformation will remain the dominant conformation and degradation will be reduced. The assumption is that increasing thermodynamic stability will also increase pharmaceutical stability. A number of solute types (i.e., amino acids, saccharides, polyols, polyethylene glycols, and some other classes) have been found effective both in increasing thermodynamic stability and in increasing pharmaceutical stability during freezing (85, 86). These solutes are referred to as excluded solutes because such solutes are present in lower concentration near the surface of a protein. The thermodynamic consequence of such exclusion is that the protein is preferentially hydrated, and the chemical potential of the protein is increased. It may be argued that the increase in the chemical potential will be much greater for the unfolded state than for the native state, thereby increasing the free energy of denaturation and stabilizing the native conformation (85, 86). Although the increase in protein chemical potential due to solute exclusion does not always correlate quantitatively with the effectiveness of that solute as a cryoprotectant, it would be prudent to test several pharmaceutically acceptable excluded solutes (i.e., glycine, mannitol, disaccharides, polyethylene glycols) as potential cryoprotectants in cases where freezing instability might involve conformational destabilization. Obviously, polyethylene glycols would not be a good choice if oxidation were an issue. For cryoprotection, it is the concentration of the cryoprotectant in solution that is the key concentration variable, regardless of the concentration of protein in the formulation. With nonpolymer excluded solutes, relatively high concentrations (i.e., 0.2–0.5 *M*) are normally required for effective cryoprotection (85).

Stabilization during drying

In addition to the stresses that develop during freezing, drying imposes an additional stress associated with

essentially complete removal of water. Indeed, the water substitute hypothesis (41, 85–87) is based upon the proposition that a significant thermodynamic destabilization occurs when the hydrogen bonding between protein and water is lost during the last stages of drying. The use of a water substitute as a lyoprotectant allows a hydrogen-bonding interaction between protein and the water substitute, which thermodynamically stabilizes the native conformation and preserves activity. A water substitute is a moiety that is capable of hydrogen bonding to the protein surface much as water and stabilizes via a thermodynamic mechanism; that is, stabilization is achieved by maintaining the free energy of unfolding very high such that essentially all of the protein is maintained in the native conformation. However, it must be recognized that most observations can also be rationalized in terms of a purely kinetic stabilization mechanism. In general, drying is conducted at temperatures sufficiently low that the protein exists in a glassy solid state where molecular mobility is greatly restricted. It may be argued (41) that a good stabilizer is a component that effectively couples protein dynamics to the dynamics of the glass such that even if the protein is destabilized thermodynamically, motion in the protein is too slow to allow significant unfolding during the drying operation. Thus, the protein conformation is stabilized regardless of the free energy of unfolding.

Nonreducing di- and tri-saccharides such as sucrose, trehalose, or raffinose are normally good drying stabilizers (41, 85, 86). They qualify as good water substitutes and also form glasses which, via hydrogen bonding, can couple protein dynamics to matrix dynamics. Under conditions of acid pH, particularly below pH 5, trehalose is a much more effective stabilizer than are sucrose or raffinose. Sucrose and raffinose hydrolyze to their reducing sugar components much more rapidly in the solid state than does trehalose, thereby leading to degradations initiated by reducing sugars (88). The key concentration variable in drying stabilization is the weight ratio (or mole ratio) of saccharide to protein, with the weight ratio of stabilizer to protein normally being between 1:1 and 10:1. The principle here is to insure that the protein is in a matrix of the stabilizer. Thus, with dilute protein systems, good stabilization can often be obtained at rather low concentrations of stabilizer. Here, it may be desirable to employ both a bulking agent such as glycine or mannitol, as well as a stabilizer. This strategy can yield both an elegant cake structure as well as optimal stability without the high solute concentrations than can slow primary drying.

Stabilization during storage

Although the destabilization stresses during storage remain much the same as the drying stresses, the time

scale of storage is obviously much longer than the timescale of freeze-drying. In addition, the freeze-dried product is normally being stored well below its glass transition temperature, meaning molecular mobility is greatly restricted (41, 85, 86). Because of these differences, the dominant degradation pathway during storage may differ from the degradation pathway during freeze-drying. For example, deamidation of asparagine residues is a very common degradation pathway during storage but rarely is a problem during processing. This observation does not imply that deamidation is faster in the dry glassy solid than in solution, but rather is simply the result of the much longer time scale of storage. Indeed, because of the need to insure stability over the shelf life of about 2 years, storage stability normally presents a more serious problem than does stability during processing. Degradation during storage may arise from chemical degradation, such as oxidation and asparagine deamidation, and/or aggregation to noncovalent or covalent aggregates (41, 85, 86). Aggregation often means formation of a population of very large insoluble aggregates that precipitate from solution. It must be admitted, however, that the observation that the level of aggregation increases during storage does not necessarily mean that the bimolecular process of aggregation occurs in the solid state. It is also possible that only conformational changes occur during storage. Aggregation of a fraction of the conformationally modified protein could then occur instantaneously during reconstitution. The remaining fraction would then refold to the native conformation. As aggregation is normally measured in solution, it is not possible to determine just when the aggregation step actually does occur. When the amount of aggregation measured depends on the reconstitution procedure and/or the composition of the diluent (i.e., presence of surfactant) used to reconstitute (32), one would conclude that, at least in part, aggregation of (partially) unfolded protein occurs during reconstitution.

Stabilization strategies focus on three general factors: (1) specific chemical requirements, (2) physical state of the solid, and (3) structure of the protein. Depending on the degradation pathway(s) and mechanisms, any one or all of these factors could be critical. Certainly, if oxidation is a major degradation pathway, stabilization requires attention to the chemical composition of the system, including both the effects of impurities and addition of stabilizers as discussed earlier. Although pH has no real meaning in the solid state, the degree of ionization in the solid does reflect the pH of the solution from which the solid was prepared, and pH of the solution can be a major variable. Because differences in polarity of the environment between a dry solid and an aqueous solution may mean that the optimum

pH for solid stability is somewhat different than the optimal pH for a solution, some solid-state screening experiments are necessary to define the precise optimum pH for stability of the freeze-dried solid.

The physical state of the system is of obvious importance. We freeze dry to increase storage stability relative to the solution state, assuming that the restricted molecular mobility of the solid state will lead to stabilization. In general, an amorphous solid (i.e., glass) is several orders of magnitude more stable than the corresponding aqueous solution, and at least with small molecules, crystalline drugs are much more stable than glasses (89). However, proteins cannot be crystallized during freeze-drying, so the only solid-state option is a glass. Forming a glass does not insure adequate stability. Pure dried proteins are glasses and often do not have sufficient stability for long-term storage at the temperatures of interest, and excipients are added to the formulation to stabilize. Because a physical mixture of protein and excipient will not provide additional stabilization, it is necessary that the proposed stabilizer system remain at least partially amorphous and in the same phase as the protein (41, 85, 86). Further, to avoid chemical reactions between the excipient and protein, the excipient system must be inert. The most common violation of inertness is the use of reducing sugars such as lactose in an attempt to stabilize the protein. For example, while lactose will stabilize hGH against aggregation, an adduct of lactose and hGH quickly forms during storage of the freeze-dried solid (18).

Drying also removes water, a reactant in a hydrolysis reaction, and stability is normally best at very low water content (41, 85, 86). However, the effect of residual

Fig. 12 The effect of residual water on the glass transition temperatures of sucrose and trehalose. (From Ref. 90.)

moisture on stability is far more complex than its possible role as a reactant. Residual water has a major effect on the physical state of the system in that increasing levels of residual moisture decreases the glass transition temperature of the amorphous system, thereby making the system less solid-like at a given temperature, and eventually causing the glass to transform into a fluid at the storage temperature. Figure 12 illustrates the effect of residual moisture on the glass transition temperature of two common stabilizers, sucrose and trehalose (90). For both examples, small amounts of residual water greatly depress the glass transition temperature, but since dry sucrose has a much lower glass transition temperature than does dry trehalose, the water content that gives a glass transition temperature at room temperature, W_g (25 °C), is much lower for sucrose. Thus, in applications where maintaining very low water

content is difficult, trehalose is a better choice for a stabilizer than is sucrose.

Generally, chemical and physical stability decrease sharply as the system enters the fluid state (41, 86, 91, 92). Chemical degradation of hGH in a trehalose formulation illustrates this behavior (92). The trehalose formulation shows a well-defined glass transition temperature with DSC, with the expected decrease in T_g as the water content is increased. The rate constant for chemical degradation is essentially independent of water content while the system remains glassy, but at least for the 50°C data, degradation increases sharply as increasing water content depresses the system glass transition temperature significantly below the storage temperature (Fig. 13). Rates of aggregation show essentially the same behavior (92). However, as stability is not sensitive to water content in the glassy state, stability is not correlated with $T - T_g$ below the glass transition temperature. The study of

Fig. 13 Chemical degradation in freeze dried hGH formulated with trehalose as a function of water content at 40°C and 50°C. The pseudo first-order rate constant for degradation (%/month) is given for the combination of asparagine deamidation and methionine oxidation. The formulation is hGH:trehalose in a 1:6 weight ratio with sodium phosphate buffer (pH 7.4) at 15% of the hGH content. The highest moisture content samples were collapsed after storage at both 40°C (moderate collapse) and 50°C (severe collapse). The water content that reduces the glass transition temperature of the formulation to the storage temperature is denoted “Wg.” Open circles = 40°C storage; filled squares = 50°C storage. (From Ref. 86.)

Fig. 14 The effect of excipients on the storage stability of freeze-dried human growth hormone (hGH). Samples were stored for 1 month at 40°C. Solid bars: aggregation (primarily dimer), shaded bar = chemical degradation via methionine oxidation and asparagine deamidation. The glass transition temperatures of the initial freeze-dried formulations are given above the bars when a glass transition temperature could be measured by DSC. The glycine:mannitol formulation is a weight ratio of hGH:glycine:mannitol of 1:1:5, the dextran formulation is 1:6 hGH:dextran 40, none means no stabilizer, and the others are 1:1 hGH:stabilizer. All formulations contain sodium phosphate buffer (pH 7.4) at 15% of the hGH content. Initial moisture contents are all $\approx 1\%$. (From Ref. 86.)

formulation effects on hGH stability suggests the same conclusion. Chemical and aggregation stability of hGH in several formulations is compared in Fig. 14 (92). The glycine:mannitol formulation is a 1:1:5 weight ratio of hGH:glycine:mannitol, where only the mannitol is crystalline. The other formulations are 100% amorphous. Hydroxyethyl starch (HES), stachyose, and trehalose are formulated in a 1:1 weight ratio of excipient:hGH, whereas the dextran formulation is 6:1 dextran:hGH. While the concept that an excipient system must remain at least partially amorphous to improve protein stability is not in question, it is clear that remaining amorphous is not a sufficient condition for stability. Apparent aggregation in the dextran formulation is greater than in the pure protein. Hydroxyethyl starch shows a slight improvement in stability over the pure protein, but is not nearly as effective as the glycine:mannitol formulation, and increasing the level of HES to 3:1 HES:hGH does not improve stability (92). Conversely, both stachyose and trehalose provide better stability than the glycine:mannitol system does, with trehalose superior to stachyose. All systems are glasses at the storage temperature of 40°C, and for those formulations where glass transition temperatures are available, it is clear that storage is well below the T_g , and there is no simple relationship between T_g and stability. Although one might speculate that a glass is more solid, and therefore more stable, the larger the difference between T_g and the storage temperature, the data are not consistent with this speculation. Comparing the stachyose and trehalose formulations, which are both 1:1 formulations with hGH, the T_g of the stachyose formulation is nearly 20°C higher than that of the trehalose formulation, but trehalose offers slightly better stability than does stachyose. These observations and other similar results (92) suggest that while it is necessary for the formulation to have a T_g well above the highest anticipated storage temperature for both elegance and stability reasons, stability well below T_g is not directly related to the precise difference between storage temperature and T_g .

The lack of a clear correlation between stability and T_g for systems well below T_g is not entirely unexpected. Molecular mobility slows greatly below T_g , but does not approach zero until some temperature much lower than T_g (41, 86). Thus, dynamics in the glass depend not only on the value of T_g but are also extremely sensitive to other characteristics of the glass as well as the thermal history of the glass (41, 93). Even if the major component of the glassy matrix (i.e., the sucrose) were to have essentially zero mobility (i.e., negligible translational and rotational motion), mobility of small molecules (i.e., diffusion of water) could still be significant, and mobility of potentially reactive groups on the protein (i.e., asparagine side chain)

could be sufficient to reorient into the transition state and react (41). Thus, it is not only necessary that the matrix itself be solid-like, but effective coupling between matrix mobility and the mobility critical for degradation is needed for solid-like stability behavior (41). Although the molecular characteristics required for effective coupling are not fully understood, it does seem that hydrogen bonding between protein and stabilizer provides one coupling mechanism (41, 86). Thus, disaccharides and trisaccharides are effective stabilizers.

With proteins, structure is also a critical stability variable. It is now common knowledge that proteins often suffer significant conformational changes on freeze-drying that may be moderated by addition of stabilizers to the formulation (41, 85, 86). In principle, different conformations may have different stability characteristics with the native conformation normally believed to represent the most stable conformation (41, 85, 86). Indeed data for rIL-2 show a strong correlation between storage stability and structure as measured by Fourier transform infrared spectroscopy (FTIR) (21), with a more native conformation associated with greater storage stability. Likewise, formulations of freeze-dried hGH having more native-like conformations are more stable to both aggregation and chemical degradation during storage (92). Thus, degradation of a protein in any given formulation is a function of the distribution and reactivities of the protein substates created during the freeze-drying process, with greater stability being associated with the more native-like substates. From this viewpoint, a good stabilizer is one that maximizes the population of native-like substates. Empirical evidence suggests that disaccharides perform this function quite well, regardless of what mechanism might be postulated to explain the observation (41, 85, 86).

In summary, guidelines for stabilization during storage involve the following principles: 1) optimize pH and address specific chemical effects such as oxidation; 2) disperse the protein in an inert glassy matrix with strong coupling between protein dynamics and matrix dynamics to form an amorphous phase such that at all residual water contents and storage temperatures of interest the protein phase will be well below its glass-transition temperature (note that this requires both protein and stabilizer exist in the same glassy phase); 3) employ a formulation (and process) such that the dried protein will retain the native conformation.

Retention of native conformation, coupling of protein mobility with matrix mobility, and formation of a single phase with the stabilizer all require an excipient that interacts, probably via hydrogen bonding, with the surface of the protein. Little or no interaction would likely lead to

Table 3 Glass transition temperatures, (T_g), of selected excipients measured by differential scanning calorimetry^a

Compound	T_g (°C)	Reference
Citric acid	11	94
Glycine	(≈ 30) ^b	66
Lactose	114	95
Maltose	100	95
Mannitol	13	74, 96
Raffinose	114	95
Sorbitol	-1.6	96
Sucrose	75	95
Trehalose	118	95
Maltodextrin 860	169	95
PVP K90	176	95

^aConsult the references for details of the techniques.

^bValue in parentheses is extrapolated from mixtures using the Fox equation and is highly approximate.

phase separation, poor coupling of protein mobility with matrix mobility, and no opportunity for the excipient to stabilize the native conformation by either water substitution or immobilization of the protein. Disaccharides (i.e., sucrose and trehalose) and trisaccharides (i.e., raffinose) seem to satisfy these criteria and are generally good stabilizers. Polymers are generally much less effective. A product glass-transition temperature well above all anticipated storage conditions is an important product quality attribute. Glass transition temperatures of selected amorphous excipients are given in Table 3. Both trehalose and raffinose have much higher glass transition temperatures than does sucrose, and in this sense, would be better choices for stabilizers. However, as long as the residual water content is maintained low and the product is not plasticized by other low-molecular-weight formulation components, a sucrose formulation will be well below its glass-transition temperature at all practical storage temperatures. Due to a very low T_g , sorbitol should not be used as a major formulation component. Incomplete crystallization of glycine or mannitol may also lead to low product glass-transition temperatures. Lactose and maltose have high glass transition temperatures but are reducing sugars and, therefore, are poor stabilizer candidates. As noted earlier, applications at low pH pose problems for both sucrose and raffinose due to rapid hydrolysis to the reducing sugar components. Trehalose is a better choice for low pH applications.

As with drying stabilization, stabilization of a protein for storage with saccharides generally requires a weight ratio of stabilizer to protein between 1:1 and 10:1, with better stabilization at the higher excipient levels. At least for hGH, the rate constants for degradation (chemical

degradation and aggregation) decrease linearly on a plot of the logarithm of rate constant as a function of stabilizer:hGH weight ratio (92). With high dose products where the protein concentration in the fill solution is high, use of high ratios of stabilizer to protein may not be feasible due to the extremely high concentration of stabilizer that would be required.

FOOD AND DRUG ADMINISTRATION: ROLE IN DRUG REGULATION

Roger L. Williams

U.S. Pharmacopeia, Rockville, Maryland, U.S.A.

OVERVIEW

With a FY2000 budget of \$395 billion and employees numbering over 61,000, the Department of Health and Human Services (DHHS) is one of the largest departments in the administrative branch of the United States Government. It is responsible for the activities of 11 operating divisions,^a including the Food and Drug Administration (FDA) (1). Although FDA's budget and staff are comparatively small (FY2000 \$1.1 billion and 9000 employees), FDA has broad authority and impact. FDA regulates approximately \$1 trillion worth of products that are sold in the United States, accounting for about 25% of products purchased by consumers annually and affecting some 95,000 businesses whose manufactured goods fall under FDA regulation. FDA activities work to assure that: 1) foods are safe and wholesome; human and veterinary drugs, human biological products, and medical devices are safe and effective; cosmetics are safe; and radiation-emitting consumer products are safe; 2) regulated products are honestly, accurately, and informatively represented; and 3) regulated products are in compliance with FDA regulations and guidelines, noncompliance is identified and corrected, and any unsafe or unlawful products are removed from the marketplace.

FDA is directed by the Commissioner of Food and Drugs whose appointment by the DHHS Secretary is subject to confirmation by the United States Senate. The Office of the Commissioner includes eight subsidiary offices. These are Chief Counsel; Equal Opportunity; Administrative Law Judge; Senior Associate Commissioner; International and Constituent Relations; Policy, Planning, and Legislation; Management and Systems; and Science Coordination and Communication. In addition, the Office of the Commissioner directs the activities of five

Centers that are responsible for many of the primary regulatory activities of the Agency. These are the Center for Biologics Evaluation and Research (CBER); the Center for Devices and Radiologic Health; the Center for Drug Evaluation and Research (CDER); the Center for Food Safety and Applied Nutrition; and the National Center for Toxicological Research. The first three of these Centers direct activities that result in the availability of many therapeutic products—drugs, biologics, and devices—to treat and prevent human disease. The Commissioner of Food and Drugs also directs the activities of the Office of Regulatory Affairs, which is responsible for FDA's enforcement activities and oversees the activities of more than 1100 field inspectors.

FDA activities are complex, challenging, science-based, and continually changing to meet societal needs and expectations. This article provides a brief overview of these activities, with the understanding that careful study and analysis may be needed to fully understand and adhere to the science, technical and legal conditions that underlie FDA's actions. Many articles and books have been published delineating FDA's statutory and regulatory mandates, to which the reader is referred (2a, 2b, 2c). FDA's web page at <http://www.fda.gov> also provides additional useful information.

LEGISLATION

The Food, Drug, and Cosmetic Act

FDA operates in accordance with provisions of the Federal Food, Drug, & Cosmetic Act (FFDCA) (3) the Public Health Service Act (4), and other laws (5). Although the principle regulatory agency for food and drugs, FDA works cooperatively with other federal agencies, such as the Environmental Protection Agency and the Department of Agriculture, and with state governments. Regulation of food and drugs by FDA dates back almost 100 years to passage of the Federal Food and Drugs Act in 1906. This law was enacted because of widespread concern about patent medicines and food quality in the US. It created

^aThe remaining are the National Institutes of Health, the Centers for Disease Control and Prevention, the Agency for Toxic Substances and Disease Registry, the Indian Health Service, the Health Resources and Services Administration, the Substance Abuse and Mental Health Services Administration, the Agency for Healthcare Research and Quality, the Health Care Financing Administration, the Administration for Children and Families, and the Administration on Aging.

important concepts that continue to the present, namely, that foods and drugs marketed in the United States should not be misbranded, i.e., should not make unsubstantiated claims or otherwise present misleading information, and should not be adulterated. The next major drug regulatory legislation after 1906 was the FFDCA itself, which was enacted in 1938 in response to the Elixir of Sulfanilamide tragedy. Using the excipient diethylene glycol to solubilize the sulfa drug, sulfanilamide, the Elixir was a potent nephrotoxin that killed over 100 children and adults. It was marketed without provision of any kind of information to FDA. In response, the 1938 law created a safety standard that requires performance of adequate tests using reasonable methods to demonstrate that a product is safe. An important feature of the 1938 legislation was and remains a requirement for premarket provision of safety information to FDA, with authority given to the Agency to confirm that the information did in fact support a determination of a safety. The 1938 approach was based on notification instead of premarket approval. If an applicant did not hear from the FDA within 60 days of filing an application it could market the product. The 1938 legislation also established the general approach, still current, that FDA for the most part responds to data developed by sponsors and applicants. FDA usually does not by itself develop data for a regulatory submission, although it frequently engages in sampling and testing of unapproved and approved products. The 1938 legislation introduced other approaches that continue to this date. For example, the concept that certain therapeutic products should bear adequate directions for use and that, in certain instances, some products may be administered only by prescription (Rx Legend) was introduced in the 1938 legislation. This distinction between Rx and over-the-counter (OTC) drugs was further elaborated in the 1951 Durham–Humphrey amendments to the FFDCA.

Many major amendments have been made to the FFDCA since 1938. The most important of these were the 1962 Harrison–Kefauver amendments that arose as a result of the thalidomide tragedy. These amendments created many provisions that form the basis for modern drug regulation by the Agency. The legislation established a premarket process that allows the FDA to judge the safety and efficacy of drugs before they can be legally marketed. It also created a requirement for submission of an Investigational New Drug (IND) application to allow distribution and study of an unapproved new drug. To document efficacy of a new drug, the legislation created an ‘efficacy standard’ requiring substantial evidence of effectiveness based on adequate and well-controlled efficacy studies submitted by an applicant. The 1962 legislation also stated that drugs be produced in

accordance with current Good Manufacturing Practices and expanded substantially the information required in product labeling.

Beyond the 1938 establishing legislation and the 1962 amendments, many other significant legislative changes to the FFDCA have occurred. These include the 1972 Drug Listing Act (established a notification process for commercially marketed products); the 1976 Medical Device Act (created Class I, II, and III types of devices based on risk, with premarket clearance required for Class III); the Drug Price Competition and Patent Term Restoration Act of 1984 (finalized approaches that allow marketing of therapeutically equivalent generic drugs coupled with patent term extension and exclusivity provisions to reward innovation); the Orphan Drug Act of 1983 (creates incentives to develop drugs for rare diseases); the Drug Export Act of 1996 (allows export of unapproved products with certain stipulations); the Prescription Drug Marketing Act of 1987 (protects against diversion of prescription drug products from well-controlled distribution channels); the Generic Drug Enforcement Act of 1993 (debars individuals convicted for illegal activities related to the approval of Abbreviated New Drug Applications); the Prescription Drug User Fee Act (requires payment for review of new drug and analogous applications and certain supplements, plus annual establishment and product fees); and the Dietary Supplement and Health Education Act of 1994 (creates a food category for dietary supplements and establishes a premarket notification process for dietary supplements entering the market after 1994). The most recent legislative amendments to the FFDCA, which also affects the Public Health Service Act, is the 1997 Food and Drug Administration Modernization Act (FDAMA) (6, 7). Many of the elements of drug regulation, as exemplified in the provisions of the FFDCA, have arisen as a result of a finding of or concern for societal risk. In contrast, FDAMA was designed to address a somewhat different perception of risk, namely, that FDA reform was needed to accelerate the availability of new medicines. This perception arose from the belief that an excessively restrictive Agency could create risk by reducing the availability of new therapeutic products. FDAMA focused on improving all aspects of FDA’s regulatory activities, including drugs (Title I), devices (Title II), foods (Title III), coupled with more general changes and requirements (Title IV). FDAMA codified many FDA initiatives previously expressed in regulations or guidance, including: 1) harmonization of measures to regulate the manufacture of drugs and biologics; 2) elimination of the need for insulin batch certification; 3) withdrawal of the distinction between antibiotics and drugs; 4) strategies to streamline approval of drug and antibiotic

manufacturing changes; 5) reduction in the need for environmental assessments; and 6) FDA's rules on accelerated approval of specified investigational drugs. FDAMA also codified FDA's practice of allowing one clinical investigation as the basis for product approval in certain circumstances, while generally preserving the 1962 standard for more than one adequate and well-controlled studies to prove efficacy. FDAMA also changed FDA's policies in many important areas, including allowance of a firm to disseminate peer-reviewed journal articles about an off-label indication of its product with certain stipulations, and allowance of drug companies to provide economic information about their products to formulary committees, managed care organizations, and similar large-scale buyers of health-care products. FDAMA created a special exemption for pharmacy compounding with certain stipulations to prevent pharmaceutical manufacturing under the guise of compounding.

The Public Health Service Act

An additional important set of Federal laws, even older than the FFDCA, relates to the regulation of biologic products. Following the deaths of 12 children from poor quality diphtheria antitoxin, Federal laws were created in 1902 to require the licensing of biologic products. FDA now regulates these under the provisions of the Public Health Service Act, which defines a biologic product as "a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product, or arsphenamine or derivative of arsphenamine, applicable to the prevention, treatment or cure of a disease or condition of human beings." Biologic products are generally derived from living organisms. Because biologic products are also defined as "drugs" and/or "devices," they are subject to the adulteration, misbranding, and registration provisions of the FFDCA. The importance of the 1902 legislation expanded with availability of therapeutic products produced through recombinant biotechnology approaches. These products fall under the Public Health Service Act as "analogous products" and may be subject to the jurisdiction of CBER. Inter-center agreements at FDA allow review and approval of drugs and biologics produced through recombinant technology in other centers as well.

REGULATIONS

FDA implements the statutory provisions of the FFDCA and PHS Act and associated laws through regulations. Regulations are rules that generally have the force of law.

They provide more explicit information about how a business or manufacturer should conduct their operations and submit information to FDA to be in compliance with the law. For example, the stipulation for adequate and well-controlled investigations stated in the 1962 amendments to the FFDCA was elaborated in a regulation that provides more explicit statements on what constitutes an adequate and well-controlled study. Other important regulations issued by FDA over the last several decades include the 1981 regulation Protection of Human Subjects; Informed Consent; Standards for Institutional Review Boards (clarifies or creates requirements for informed consent and institutional review boards to protect human subjects participating in FDA regulated research) and several regulations designed to accelerate the availability of investigational and approved drugs to treat life-threatening illnesses such as HIV and cancer (1987 Treatment Use of Investigational New Drugs, 1988 Procedures for Subpart E Drugs, 1992 Accelerated Approval, 1992 Parallel-Track Mechanism). A public process exists that allows interested parties to view and comment on preliminary (Announced Notice of Proposed Rule-Making) and draft (Proposed Rule-Making) FDA regulations before they are finalized (Final Rule). Provisions of the Federal Administrative Procedures Act govern the overall process, including the Agency's response to public comments. FDA regulations are published and updated annually in the Code of Federal Regulations (CFR).

GUIDANCES FOR INDUSTRY

FDA uses guidance documents as a means of communicating to regulated industry and the public at large about ways to meet its governing laws and implementing regulations. While guidance documents have been used over the years under many names, FDA began producing them regularly in the mid-1980s as one of three phases of a comprehensive effort to improve the IND/NDA process. Guidances assist sponsors and applicants in understanding how applications should be formatted and what they should contain, how regulated industry should comply with regulatory directives, how inspections should be conducted, and how to comply with many other regulatory activities. The use of guidances has increased as a result of international harmonizing activities, such as the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), the Veterinary International Conference on Harmonization for veterinary products, and the Global Harmonization Task Force for devices. To facilitate

development, issuance, and use of guidance documents, the Agency published a 1997 Good Guidance Practices document (62 FR 8967) that articulated the purpose, definition, legal effects, procedures for development, standard elements, implementation, dissemination, and appeals for Agency guidances. As part of this effort, the FDA committed to publish semiannually possible guidance topics or documents for development or revision during the next year, and to seek public comment on additional ideas for new or revisions of existing guidance documents (63 FR 59317). Many guidances have been produced by FDA over the last several years to assist sponsors and applicants. Although FDA guidances do not have the force of law, they indicate the Agency's best judgment about the amount and type of information needed to satisfy the Agency's legal and regulatory requirements. Regulated industries and businesses do not need to follow guidance recommendations if they wish to employ alternative methods that are acceptable to FDA. In accordance with a requirement of the 1997 FDAMA legislation, FDA is converting its Good Guidance Practices document into a regulation (8).

GUIDANCES FOR REVIEWERS

While most FDA guidances are directed to regulated industries, some are directed to Agency review staff in the form of Good Review Practices documents. These guidances instruct FDA review staff on how to conduct a high quality, consistent, timely review of an application or supplement. Good Review Practices documents may be viewed as one element in a series of quality control elements for regulatory review processes that also include secondary and tertiary supervisory oversight of a primary review, review templates, training, internal standard operating procedures, and many other initiatives as well. Good Review Practices documents complement Agency guidances and are also developed in accordance with the Agency's Good Guidance Practices document. Although Good Review Practices documents and internal standard operating procedures are directed at agency staff, they are of substantial interest to regulated industry and serve as a means of promoting transparency about Agency functions to pharmaceutical sponsors and the public at large.

DRUG REGULATION AT FDA

The FFDCA defines drugs as "articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals" and "articles (other than

food) intended to affect the structure or any function of the body of humans or other animals." The therapeutic use defines whether an article is a drug. Thus, FDA may consider a food, cosmetic, and dietary supplement to be a drug if they are associated with a therapeutic claim. The FFDCA also defines a drug as an article recognized in the official United States Pharmacopeia, official Homeopathic Pharmacopeia of the United States or official National Formulary, or any supplement to these documents. The concept of new drugs arose with the 1938 legislation. FDA allows "grandfathered" drugs marketed in the United States prior to 1938 to remain in the market providing they are generally recognized as safe (GRAS) and effective (GRAE). After the 1938 and 1962 legislation, all new drugs require Agency review and approval before they can be marketed. Recognizing that "new drugs" may be considered by several FDA Centers, information about most new drugs, including both prescription pioneer, generic equivalents, and OTC drugs, is submitted in new drug applications (NDAs) or abbreviated new drug applications (ANDAs), and supplements and annual reports for these applications to CDER. Most of the following discussion thus relates to the regulation of new drugs as executed by this Center. Many elements considered in this discussion are also applicable to biologic products submitted to CBER. Note: Two licenses are necessary to manufacture and distribute some biological products—one for the product (Product Licensing Application/PLA) itself and one for the establishment where it is manufactured (Establishment Licensing Application/ELA). Others only require one application, termed a Biologics Licensing Application, which covers both the product and its manufacture.

DRUG DEVELOPMENT AND APPROVAL

Discovery, development, regulatory assessment with possible approval, and post-marketing manufacture, distribution, and marketing of a new drug is a complex series of activities that is highly resource intensive. Modern drug discovery and development occurs primarily in laboratories of the pharmaceutical industry and in academic and government research centers as well. The loss rate is large, with thousands of drugs screened in early laboratory and animal studies before a few are considered suitable for studies in humans. Information about early discovery and nonclinical animal studies is submitted to the Agency in an Investigational New Drug (IND) application. This part of the regulatory process relies on notification, so that a sponsor may proceed with clinical studies in humans if the Agency does not respond with

30 days of submission. Regulations giving provisions of the IND process are provided at 21 CFR 312 and in further agency guidances (e.g., the FDA guidance *Content and Format of INDs for Phase 1 Studies of Drugs, Including Well-Characterized Therapeutic Biotechnology-Derived Products* (9)). CDER receives approximately 1500 INDs each year, most of which represent individual investigator INDs. Approximately 400 of these are commercial ones submitted by pioneer manufacturers. A key provision of the IND process—and for many clinical studies of approved drugs as well—is the protection of human research subjects, which should occur according to the stipulations of the 1981 informed consent and institutional review board regulations.

After filing an IND, a sponsor conducts nonclinical and clinical studies to assess the safety, efficacy, and quality of an investigational new drug. Information from these studies is collected into an NDA and submitted to FDA for review. These studies involve characterization of the new drug for its important safety, efficacy, and quality attributes. The IND process may take many years and include scores of nonclinical and clinical studies. The studies move through discrete phases. The first phase (Phase 1) group of studies focus on safety coupled with pharmacokinetic and pharmacodynamic studies in small numbers of usually healthy subjects. The studies continue with patient studies to explore efficacy (Phase 2, sometimes termed proof of concept studies) and conclude with additional studies in larger numbers of patients to assess safety further and confirm efficacy (Phase 3). Many additional studies may be performed in association with these primary studies to assess the influence of concomitant medications (drug–drug interaction studies), bioavailability and bioequivalence, subpopulation effects, and other findings that may be useful to practitioners, patients, and consumers in understanding how to use the new drug optimally. While many drugs follow the sequences defined in Phases 1–3, this is not always the case. Depending on an investigational drug's intended indications, its safety profile, its therapeutic need and many other factors, many modifications to the general sequence may occur.

Most NDAs and ANDAs are approved at FDA by CDER. In a single year, the Center approves approximately 100 NDAs, with approximately 30% of these representing previously unapproved new molecular entities (NMEs). The remainder represent line extensions, e.g., new dosage forms, new routes of administration. In addition, CDER approves many thousands of supplements to NDAs each year, most of which represent manufacturing changes but many of which represent supplements providing information about new uses (efficacy supplements) or additional safety information. CDER also has

responsibility for considering annual reports that are required for each approved NDA and ANDA. With a review staff of approximately 1700, CDER is organized into several main units. One of the most important of these is the Office of Review Management that oversees the activities of five Offices of Drug Evaluation (I–V). These Offices in turn are responsible for the activities of 15 review divisions that are organized primarily according to therapeutic groups and drug classes. For example, the Division of Cardio-Renal Drug Products reviews applications that are for new drugs used to treat cardiovascular and renal diseases. The Office of Review Management also comprises an Office of Biostatistics and an Office of Post-Marketing Drug Risk Assessment. The former office reviews statistical analyses in applications and supplements, while the latter office focuses on post-marketing adverse drug reports. A further primary unit in CDER is the Office of Pharmaceutical Science. This Office has responsibility for the Offices of New Drug Chemistry, Clinical Pharmacology and Biopharmaceutics, Office of Testing and Research, and Office of Generic Drugs. Additional administrative and regulatory activities in CDER, including those involving compliance, are handled at the level of the Center. CDER works closely with many Centers at FDA, including CBER and CDRH, and perhaps most notably with the Office of Regulatory Affairs, which is responsible for assuring that firms manufacture products in accordance with current Good Manufacturing Practices (cGMPs). Additional inspections to assure compliance with Good Laboratory Practices (GLPs) and Good Clinical Practices (GCPs) are conducted by CDER.

INDs and NDAs

From a science and technical standpoint, a good conceptual understanding has emerged in the last several decades about the IND processes that result, finally, in a safe, effective, and good quality new drug product. According to this understanding, a drug substance (active ingredient/active moiety and nonactive components, e.g., impurities, residual solvents) is combined with excipients to create a pharmaceutical product with defined identity, strength, quality, purity, and potency. An associated aspect of quality relates to product performance. Performance is assessed by product quality bioavailability and relative bioavailability (bioequivalence) studies. These studies measure the rate and extent of release of the active ingredient from a drug product and its subsequent availability to one or more sites of action. At these sites of action, the active ingredient and/or its metabolites produce the safety and efficacy outcomes reflected in product labeling. Safety, efficacy, and quality topics in

drug development and regulation can be expressed via a set of questions (primary question, test to address the question, and confidence needed in analysis of test outcome) that allow a basis for mutual understanding. From a regulatory perspective, the first set of questions can usually be stated simply (does the new drug have good quality? is it safe? is it effective?). These are the questions that drive nonclinical and clinical characterization studies conducted during the IND period and that lead to a set of data that is submitted in an NDA. Following regulatory assessment and approval if indicated, these characterization studies result in product labeling that provide instructions for use by the practitioner for prescription drug products and by the patient and/or consumer for OTC products. With Agency approval, an applicant may manufacture, distribute, advertise, and sell the approved new drug product throughout the United States market.

An NDA submission includes the following six technical sections: 1) Clinical; 2) Human pharmacokinetics and bioavailability; 3) Chemistry, manufacturing and controls; 4) Microbiology; 5) Nonclinical pharmacology and toxicology; and 6) Statistics. Further information about some of these sections is considered briefly in the following sections. More detailed information is provided in FDA regulatory documents and in internet and print publications. Examples include *the CDER Handbook* (10) and a recently updated document entitled *From Test Tube to Patient: Improving Health through Human Drugs* (11).

Clinical Information

FDA's focus on efficacy began in 1962, was further elaborated in regulations, was modified by FDAMA, and has been considered in detail in an Agency guidance entitled *Providing Clinical Evidence of Effectiveness for Human Drug and Biological Products* (12). Data from clinical studies containing efficacy data are a primary component of any NDA. These data are judged by FDA review staff to establish effectiveness of a new drug for one or more indications. A core set of guidances, many developed in ICH, also provide basic recommendations on the conduct of clinical studies needed to establish efficacy. In addition, FDA has published many guidances that provide recommendations on clinical trial design approaches, therapeutic endpoints, and other factors to consider in planning clinical safety and efficacy studies for specific disease categories or drug classes. Depending on the drug class, therapeutic indication, and therapeutic need, FDA has substantial latitude in defining the types and amount of information needed to establish safety and efficacy. While full documentation of clinical benefit information, such as reduction in morbidity and mortality,

may be needed to support approval of many new drugs, FDA may rely on lesser information for investigational drugs where a critical therapeutic need exists. For example, FDA may rely on surrogate markets instead of clinical benefit markets to allow approval, with the understanding that additional clinical benefit information may be requested after marketing.

Unlike many other regulatory agencies, FDA encourages frequent meetings with sponsors during the IND period so that good communication occurs about the information that will be needed in an NDA. In the final analysis, this information must convince Agency review staff that adequate and well-controlled studies provide substantial evidence of effectiveness and that study results also show that a product is safe under the conditions of use in the proposed labeling. Overall, the benefits arising from use of the new drug product must outweigh its risks. Risk/benefit judgments are frequently challenging for the applicant, the FDA, and the public at large. For drugs used to treat benign, self-limited conditions, little risk may be tolerated. Larger degrees of risk may be acceptable for drugs used to treat serious and life-threatening illnesses. Both during and after approval, information about safety of a new drug is required through many Agency laws and regulations. During the IND period, many of these requirements are designed not only to provide information about adverse drug reactions but also to protect human subjects participating in clinical trials. After approval, the agency requires product manufacturers and certain health care facilities to report adverse drug events. FDA developed a MedWatch program with a common reporting form and contact points to facilitate reporting of serious adverse events by health care professionals and consumers. MedWatch covers not only new drug products regulated by CDER but also biologics and medical devices. Information from safety reporting may enter product labeling and otherwise impact on the availability of a new drug product to practitioners and consumers. Although rare, withdrawal of an approved new drug product from the market may occur if a pharmaceutical manufacturer and the FDA agree that its benefits no longer outweigh its risks.

Pharmacokinetic and Bioavailability Studies

Pharmacokinetic and bioavailability studies and other clinical pharmacology studies have taken on increasing importance in the set of nonclinical and clinical studies that are performed during the IND period. This has occurred in part as a result of increasing capability to measure an active ingredient/moiety and its metabolites in accessible biologic fluids over time (pharmacokinetic studies). It has also occurred with increasing capability to

study the time course of drug effects (pharmacodynamics) relative to exposure, which can be expressed in terms of either dose or systemic concentration. In addition, most investigational new drugs enter the clinic with a better mechanistic understanding of how positive and negative effects occur in relation to the pathophysiology of disease. A focus of these studies relates to an understanding of an optimal dosage regimen in the population and in an individual. Clinical pharmacology information supports adjustment in dosage regimens based on intrinsic (e.g., genetic polymorphisms, age, gender, height, body mass and composition, and organ dysfunction) and extrinsic factors (e.g., diet, smoking, alcohol intake, concomitant medications). Adjustments in a dosage regimen according to these factors have become of increasing importance. For example, several drugs have been withdrawn from the market in recent years because of dangerous adverse drug reactions (mibefradil, terfenadine, hismanal, cisapride). Dose optimization pharmacokinetic and pharmacodynamic studies, including subpopulation and drug–drug interaction studies, are now performed frequently, in addition to the more routine absorption, distribution, metabolism, excretion (ADME) pharmacokinetic studies that have been performed for many years. A good understanding of exposure–response relationships may also support risk/benefit judgments of safety/efficacy data.

Bioavailability and Bioequivalence

Product quality bioavailability and bioequivalence studies are also an important part of the information needed to support an FDA approval (13). For most orally administered drugs, BA and BE measures are frequently expressed in terms of systemic exposure measures such as area under the plasma concentration–time curve (AUC) and maximum concentration (C_{\max}). These measures of systemic exposure link with safety and efficacy outcomes that may be expressed in terms of biomarkers, surrogate endpoints, or clinical benefit endpoints. Studies that can meet the intent of these regulations for orally administered and certain other drug products have been elaborated in greater detail in an FDA guidance entitled *Bioavailability and Bioequivalence Studies for Orally Administered Drug Products—General Considerations* (14). Bioavailability and bioequivalence studies document that the performance of a drug product is reliable and consistent. This is important not only as part of the new drug approval process but also in the presence of postapproval changes in the components and composition of an approved drug product and/or its method of manufacture. Depending on the magnitude of these changes, redocumentation of bioequivalence may be needed after approval. Relative BA

studies are useful in comparing the systemic exposure profiles of different dosage forms. In this context, BA information, sometimes together with pharmacokinetic and pharmacodynamic and other data, can be used to link the performance of two different dosage forms and assure comparable clinical outcomes.

Chemistry, Manufacturing and Controls, and Microbiology

During the IND period, sponsors characterize the drug substance and drug product sufficiently so that important quality attributes are established and controlled. This effort focuses on: 1) the drug substance, to assure identity and strength of the active ingredient(s) and to control impurities arising from production and/or degradation; 2) the drug product, to assure the identity and strength of the active ingredient(s) and to monitor degradants that may arise during manufacture and storage; 3) the container–closure system, to protect the drug product during storage; 4) stability testing to assure maintenance of quality attributes during shelf-life; and 5) container labeling. For sterile pharmaceutical products, special approaches are needed. Full understanding of the manufacturing processes for a finished drug product also requires an understanding and application of in-process controls and of the quality of manufacturing materials even when they are not present in the final drug product. Using characterization data, a sponsor develops a set of specifications to assure the identity, strength, quality, purity, and potency of the product and to allow batch release into the marketplace. A specification is defined as a list of tests, references to analytical procedures to evaluate those tests, and the appropriate acceptance criteria. Specifications allow a determination that a particular drug substance or drug product can be considered acceptable for its intended use. Specifications are needed for the drug substance, the drug product, and the container and closure. They may also be needed for intermediates, raw materials, reagents, and other components, including container and closure systems and in-process materials. Specifications are one part of a total control strategy for the drug substance and drug product designed to ensure product quality and consistency. Adherence to current Good Manufacturing Practices is an important part of this overall strategy. Based on characterization and specification setting processes, pioneer manufacturers compile information about the quality of starting materials and their manufacture into a finished dosage form. FDA chemists review this information to assure that critical quality attributes are controlled. In addition, the chemistry review also focuses on in-process controls and validation of

analytical procedures and, for sterile drug products, process validation to assure sterility. Compendial drug substance and excipient monographs as well as general tests and procedures in the *United States Pharmacopeia and National Formulary (USP-NF)* are frequently cited in an NDA and considered during the chemistry review.

Nonclinical Pharmacology and Toxicology Studies

The purpose of nonclinical animal safety studies is to support estimation of initial starting doses in humans and to characterize toxic effects with regard to target organs, exposure, dose dependence, and reversability. This information is provided in a series of studies that focus on single and repeated dose toxicity, reproduction toxicity, genotoxicity studies, local tolerance studies and, for drugs with especial concern and/or that are intended for long-term use, on carcinogenicity. Other nonclinical studies in animals may focus on safety effects on vital organ systems and pharmacokinetic (ADME) studies. The timing of nonclinical studies is important to assure optimal and safe performance of clinical studies. A series of guidelines have become available through ICH that provide guidance on the types of nonclinical studies and their timing needed to support clinical studies of an investigational agent and product labeling for an approved new drug. These cover studies on the following general topics: carcinogenicity, genotoxicity, pharmacokinetics, toxicity, reproductive toxicity, study of biotechnology products, safety pharmacology, and timing of nonclinical and clinical studies. Because this information is required to allow advance of investigational studies in the clinic, it will be submitted in reports and updates during the IND process. It may be summarized and analyzed as well in the NDA.

Biostatistics

Nonclinical and clinical development of an investigational agent requires a series of exploratory and confirmatory studies that rely on adequate statistical analyses. Careful attention is needed with regard to the many aspects of trial design to assure unbiased, robust conclusions regarding safety and efficacy. Important elements of a statistical analysis are discussed in an FDA guidance entitled *Guidance on Statistical Principles for Clinical Trials* (15).

NDA Review

Review of the information in an NDA is conducted according to time frames that are stipulated by law. These

time-frames vary depending on whether the drug merits a priority or standard review. Priority drugs represent a substantial advance over available therapy. FDA commits to reviewing these types of drugs within six months. Standard drugs are defined as having therapeutic qualities similar to an already marketed drug. FDA commits to reviewing these in 10–12 months. The outcome of the FDA's deliberations are expressed in action letters. If submitted information establishes the effectiveness and safety of the new drug, the FDA will issue an approval action letter that permits the applicant to market the approved new drug in the United States. If the information does not establish effectiveness and safety, FDA may issue a nonapprovable action letter with a request for further information. If satisfactory, this information may subsequently support FDA's issuance of an approval letter. Over the years, approximately 60–80% of NDAs are approved, with the number rising in recent years presumably as applicants develop a better understanding of the information needed in an application to establish safety, efficacy, and quality. As part of an approval, FDA may request that an applicant provide additional information as part of an approval commitment (Phase 4 studies).

To assist the Agency in its deliberations, FDA established a system of advisory committees in 1964. These committees review data and provide recommendations to the Agency about whether or not an approval should proceed, or whether some other Agency action is or is not appropriate. The Agency's advisory committees, which function generally under the 1972 Federal Advisory Committee Act, have been modified over the years. Some of these modifications occurred as result of a 1992 Agency requested review by the Institute of Medicine, which coincided with an internal Agency evaluation, and some were put in place in the 1997 FDAMA legislation. The Agency's current advisory committee system involves many committees that meet to discuss a new drug's safety and efficacy, a new indication for an already approved drug, or a special science topic or adverse event profile. FDA's advisory committees provide only recommendations, which the Agency usually follows but at times may not. Membership in an advisory committee is chosen to reflect a needed constituency for a given topic, and includes both consumer and industry representatives. Care is taken to avoid conflicts of interest, with exclusion of a member if needed or, if an individual's view is important, with waiver to allow participation according to specified criteria. Advisory committee charters must be renewed biennially by DHHS and the General Services Administration.

After an NDA is approved, a pharmaceutical manufacturer may promote and advertise the approved new drug in accordance with provisions of the FDCA and its

implementing regulations. An approved application may be supplemented with new safety, efficacy, or manufacturing information.

ABBREVIATED NEW DRUG APPLICATIONS

The 1984 Drug Price Competition and Patent Term Restoration amendments to the FDCA created an abbreviated mechanism for the approval of generic copies of drug products approved for safety and efficacy via the NDA process. Provisions of the amendments and its implementing regulations require that a generic applicant demonstrate that its product is the same as that of the corresponding innovator drug (the reference listed drug) in terms of active ingredient(s), strength, dosage form, and route of administration. These stipulations are termed pharmaceutical equivalence. In addition, the applicant must demonstrate that the labeling of its proposed generic version is comparable to that of the innovator product and that the generic product is bioequivalent to the reference listed drug. With this approach, the requirement for extensive nonclinical and clinical testing for a generic product is frequently obviated. Information developed by a generic applicant is submitted for Agency review in an ANDA if acceptable, the application is approved and the generic copy is deemed interchangeable with the corresponding reference product under specified conditions of use. As part of the 1984 legislation, an extensive series of requirements regarding patent certification and exclusivity was developed. These approaches were part of a general intent of the 1984 legislation to balance incentives for innovation with the societal need for low-cost duplicates of pioneer products.

OVER-THE-COUNTER DRUG PRODUCTS

Based on distinctions created in the 1938 FDCA and the 1951 Durham–Humphrey Act, new drugs are categorized as either prescription and nonprescription or OTC. OTC drug products are deemed sufficiently safe for self-use. While FDA applies the same standards of safety and efficacy to prescription and nonprescription new drugs, it regulates them in two ways. One is by a monograph system and the other is through switching a prescription drug approved under an NDA to nonprescription status (Rx to OTC Switch). The OTC monograph system arose out of a need to document efficacy for the many thousands of new drugs that had been approved for safety only between 1938 and 1962. This was accomplished through the Drug

Efficacy Safety Implementation (DESI) program. As part of the effort, FDA initiated an OTC Drug Review in 1972 that resulted in the development of over 100 monograph categories (e.g., antacids, laxatives) for over 500 active ingredients that were marketed between 1938 and 1962 in approximately 700,000 different dosage forms. A manufacturer may market an OTC product in one of these categories without submitting information to FDA providing the manufacture and marketing of the product conform to stipulations in the monograph and to *USP-NF* substance and product monographs if available. In addition, experience with a prescription drug after its approval may result in an understanding that its can be used safely and effectively without professional supervision. FDA has allowed this type of Rx to OTC switch, either for approved prescription new drugs or for new indications, on 66 occasions in the last five years.

THE UNITED STATES PHARMACOPEIA

Practitioners established the *United States Pharmacopeia* in 1820 to promote the availability of unadulterated and appropriately named and prepared therapeutic products. With the addition of an information component beginning in 1980, USP's role expanded from establishing standards for healthcare articles to providing useful information to assist practitioners, consumers, and patients in optimal use of therapeutic products. Section 201 (j) of the Federal Food, Drug and Cosmetic Act defines the *United States Pharmacopeia (USP)* and the *National Formulary (NF)* as official compendia. These texts provide quality standards for therapeutic products and excipients approved under the provisions of the Food, Drug & Cosmetic Act, and other therapeutic products as well. The availability of a *USP-NF* monograph requires that any drug marketed under the monograph name must comply with the specifications, irrespective of whether the article bears the *USP-NF* designation. Through the adulteration and misbranding provisions of the Food, Drug & Cosmetic Act, FDA can take enforcement action against firms whose drug products do not comply with a *USP* or *NF* standard. The letters “USP” or “NF” are not trademarked and can be utilized by companies for non-drug products if they wish as a representation of the quality of their products subject only, for the most part, to regulatory constraints. Manufacturers of drug are not required to comply with USP standards but if they choose not to do so they are required to label their product as “not USP” and indicate how their product differs on the container label. For the most part, manufacturers choose to adhere to USP standards rather than conform to this requirement.

ADDITIONAL INFORMATION

In regulating drugs, FDA is continually changing and growing as a result of societal needs, rapidly changing science and technology, and health care delivery challenges. It also must consider international activities and harmonization and carve-outs where regulatory focus is diminished or clarified. Key to all of FDA's activities is the availability of resources to allow performance of its statutory functions. Some of these issues are discussed briefly in the following paragraphs.

Resources

Until 1992, resources for FDA came from appropriated tax dollars allocated at the beginning of each year through budget processes of the Administration and Congress. In 1992, Congress enacted the Prescription Drug User Fee act (PDUFA) that authorized FDA to collect fees from the prescription drug industry to augment FDA's appropriated resources. The additional resources were to be used to expedite the review of NDAs and Biologics Licensing Applications (BLAs) so that prescription drug products could reach the marketplace more quickly. The first PDUFA program, termed PDUFA I, was enacted for a period of five years, ending in 1997. In that year, as part of FDAMA (Title 1/Subtitle A—Fees Relating to Drugs), PDUFA was reauthorized, as PDUFA II, for five more years. PDUFA I included performance goals for FDA that were coupled with FDA managerial reforms. Via fees charged for application review, more than 900 employees have been added to the Agency's new drug and biologics review programs. In 1999, approximately \$125 million in user fees were collected from the pharmaceutical industry. With these resources, CDER and CBER have generally met or exceeded the performance objectives of PDUFA I and II. PDUFA II has increased both the resources available to the FDA as well the performance objectives, e.g., by 2002, when PDUFA II ends, 90 percent of standard original NDAs and BLAs filed during FY 2002 will be reviewed and acted on within 10 months of receipt.

PDUFA provides resources only for the review of NDAs, leaving many of areas and processes of the Center still supported by appropriated dollars. Failure to increase Agency appropriations in the last several years have left many non-PDUFA components at FDA with substantially lower funding at the end of the 1990s than at the beginning. While PDUFA resources are useful, consumer groups and other have expressed concern over both undue emphasis on review timeliness and industry influence, given that a substantial fraction of the budget for new drug

reviews is now provided by industry. Recent market withdrawals have heightened this concern (16, 17), although FDA has provided data to indicate that market withdrawals diminished in frequency since PDUFA was introduced (18).

International Harmonization

FDA engages in many international activities that result in information exchange, working closely with the World Health Organization and in different types of bilateral, trilateral, and multilateral arrangements. One of the most substantial examples of this effort is ICH (19). A primary objective of ICH is to avoid duplicative animal and human testing and to come to a common understanding of technical requirements to support the registration processes in the three ICH nations/regions, which include the European Union, Japan, and the United States. ICH began in 1989 as a collaborative effort between representatives from the Food and Drug Administration working with representatives from the European Commission (at the time the Commission of the European Communities) and the Japanese Ministry of Health and Welfare, and also with representatives from the three corresponding pharmaceutical manufacturers associations, the Japanese Pharmaceutical Manufacturers Association, the US Pharmaceutical Research and Manufacturers of America, and the European Federation of Pharmaceutical Industries Associations. Observers to ICH include representatives from the World Health Organization (WHO), the European Free Trade Association, and Canada's Therapeutic Products Program. ICH has established a Steering Committee, which meets twice yearly, moving sequentially through each ICH area, to provide oversight to the ICH Expert Working Groups that focus on specific topics for harmonization. Secretariat support to ICH is provided by the International Federation of Pharmaceutical Manufacturers Association provides two representatives to the Steering Committee. The ICH Expert Working Groups focus on Efficacy (clinical safety and efficacy topics), Safety (nonclinical safety), Quality, and Regulatory Communications. ICH has established a process for guidance development that begins with identification of a topic area for harmonization, for which a concept paper is developed, collection of background information, and formation of an Expert Working Group to draft the guidance (Step 1). This initial process yields a draft guidance that moves through a multistep process that, if successful, yields a final guidance that becomes part of the regulatory machinery in the European Union, the United States, and Japan (Steps 2–5).

With this approach, ICH differs from guidances developed by the World Health Organization, which do not necessarily become binding on a regulatory agency. In the 10 years since its inception, ICH has resulted in the preparation of over 40 finalized guidelines and position papers that are designed to guide drug development and registration activities in the European Union, Japan, and the United States. A more recent focus of ICH has been the development of a Common Technical Document that will provide a core set of information to support an NDA or BLA in the US, and the corresponding application documents in Europe and Japan. ICH has confronted several issues and challenges during the initial 10 years of its existence. For example, ICH is highly resource intensive and has at times excluded interested parties and stakeholders. The issue of exclusion has been dealt with at least in part via the efforts of WHO, which has disseminated ICH draft and finalized guidelines to WHO Member States. In addition, at biennial meetings of WHO's International Conference of Drug Regulatory Authorities, presentations on the status of ICH topics has become an increasingly important part of the program.

Regulatory Control

A key question for any society is the scope of responsibility that it gives to its regulatory agencies. This scope is defined through legislative and administrative actions, through judicial decisions, and through regulatory action or inaction. In the last decade, legislative decisions have limited and/or clarified the scope of FDA's responsibilities in two important areas. Examples include the regulation of dietary supplements and pharmacy compounding. Before 1994, FDA regulated dietary supplements according to the provisions of the 1958 Food Additive Amendments to the FFDCA, which required pre-market safety review for all new ingredients, including dietary supplements. In the 1994 Dietary Supplement Health and Education Act (DSHEA), Congress added provisions to the FFDCA that eliminated requirements for pre-market documentation of safety for dietary supplements and dietary ingredients of dietary supplements (20). In accordance with the 1958 legislation, these requirements continue to apply to other new food ingredients or for new uses of old food ingredients. DSHEA and the 1990 Nutritional Labeling and Education Act (NLEA) also extended the definition of a dietary supplement from vitamins, minerals and, proteins to herbs or similar nutritional substances and substances such as ginseng, garlic, fish oils, psyllium, enzymes, glandulars, and mixtures of these. Many provisions of DSHEA are now being implemented via FDA regulations.

A particularly challenging one relates to regulations that distinguish between dietary supplement claims and drug claims. The FFDAC defines a drug as an article intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or animals. A product may be subject to regulation as a drug if it makes a claim that is other than food, and it is intended to affect the structure or any function of the body of man or other animals. Manufacturers of a dietary supplement may claim an affect on the structure and function of the body as long as they do not make drug claims. FDA has been challenged to provide a clear distinction between drug and dietary supplement claims in product labeling. This challenge reflects the boundary between food and drug claims and relates to the limitations and/or clarification in the scope of FDA's responsibilities expressed in NLEA and DSHEA. This distinction is currently provided in an FDA regulation entitled Regulations on Statements Made for Dietary Supplements Concerning the Effect of the Product on the Structure or Function of the Body (21).

Section 127 of FDAMA added section 503A of the FFDCA to clarify the status of pharmacy compounding of a drug by a pharmacist or physician on a customized basis for an individual patient. Section 503A defines pharmacy compounding to allow exemptions from the Good Manufacturing Practices, full disclosure requirements, and new drug provisions of the FFDAC. To qualify for these exemptions, a compounded drug product must satisfy several requirements delineated in Section 127. The general objective of section 127 is to allow a pharmacist and or physician to engage in the legitimate practice of compounding and to clarify the distinction between compounding and pharmaceutical manufacturing that comes under the oversight of FDA.

SUMMARY

Drugs to prevent and/or treat disease are a critical component of the U.S. health care system. The U.S. total health care bill is well over \$1 trillion, with medical products accounting for approximately 8% of this total expenditure. Both the total health care cost and the fraction of the cost represented by medical products is expected to rise substantially in the coming years. Availability of most medical products is regulated closely by FDA and is one activity in a complex set of activities by which a new drug reaches a patient. Generally, these activities may be viewed in terms of discrete yet overlapping efforts that include drug discovery, nonclinical and clinical development programs, regulatory assessment, and utilization.

Revolutionary changes are occurring in each of these four areas. Drug discovery is driven by an increasingly detailed understanding of human physiology and pathophysiology arising from the molecular biology revolution and many associated diagnostic and therapeutic advances. Molecular modeling and combinatorial chemistry combined with high through-put screens for positive and negative drug effects and biopharmaceutical properties have expanded the number of lead candidates for nonclinical and clinical development. An improved understanding of the mechanistic basis for drug absorption and disposition and drug action provides better information about drug safety and efficacy. The regulatory review process at FDA has become more timely, in part as a result of availability of resources from users' fees charged to pharmaceutical sponsors submitting NDAs for prescription drugs and certain supplements to these applications.

The utilization of drugs to maintain health and treat disease has undergone profound change in the medical community as a result of many factors, including the need to contain costs yet assure that patients have access to the latest medical treatments. Overarching these changes in discovery, development, assessment, and utilization have been revolutions in information technology, materials science, management, and many other areas. All activities associated with getting a medical product to a patient are further affected, sometimes profoundly, by national and international societal and political factors. The intensity with which FDA functions relates to countervailing forces that work to promote the availability of the latest medical products versus forces that work to focus on the safety of these products. Globalization of the pharmaceutical industry has resulted in a need to harmonize on regulatory requirements and recommendations for the development of a new drug product. From a public policy perspective, FDAMA represents societal encouragement, expressed through Congressional legislation, for FDA to act more rapidly in making regulatory decisions. Availability of users' fees has provided FDA with resources to achieve this objective. Changes arising from FDAMA and users' fees appear to represent a major transformation in societal thinking about drug regulation, which in the past has focused on an expectation the FDA should function as a gatekeeper to keep unsafe medical products and foods from the market. FDAMA and users' fees work to shift that focus to facilitation of the availability of medical and other products regulated by FDA. These changes arose in the decade of the 1990's as a result of many factors, including a long history of charges that FDA created a drug lag, availability of an increasing number of important new medical products, a rise in activism from patients with serious and life-threatening diseases such as AIDS and

cancer, and many other factors as well. As with all societal directives, opinions and forces may cause a reversal in Agency approaches. Concerns are raised now about drug safety and certain market withdrawals of unsafe drugs and drug combinations. The charge, generally refuted by FDA (18), is that a more rapid regulatory process leads to the availability of unsafe medical products.

GOOD MANUFACTURING PRACTICES (GMP)—AN OVERVIEW^a

Ira R. Berry

Duramed Pharmaceuticals, Inc., Somerset, New Jersey, U.S.A.

INTRODUCTION

The Current Good Manufacturing Practice (cGMP) regulations for finished pharmaceuticals that have been promulgated by the U.S. Food and Drug Administration (FDA) have been a subject of active discussion since they were first published with the passage of the Kefauver–Harris Drug Amendments in 1962 (1, 2). GMPs were intended to establish minimum manufacturing and control practices for the pharmaceutical industry and focus on what needed to be done rather than how it should be done. Failure to comply with the current Good Manufacturing Practice regulations as set forth in the “Code of Federal Regulations,” 21 CFR Parts 210 and 211 (3), constitutes adulteration of a drug that is entered into interstate commerce and is therefore subject to regulatory action. These requirements apply to human and animal drugs. The regulations in Part 210 are introductory in nature; Part 211 contains the more detailed and descriptive regulations and which will be discussed in this chapter.

In the late 1970s, the FDA organized a task force to study the GMPs. Revised GMPs were published in September 1978, and became official in March 1979. At that time, the FDA also considered establishing more specific GMP regulations for products such as small-volume parenterals, medicinal gases and drug substances, to supplement the existing umbrella regulations.

Today, separate GMPs are in effect for biologics and foods but have not yet been promulgated for small-volume parenterals, medicinal gases or drug substances. In attempting to create regulations for specific products, the FDA concluded that it would be better to first issue guidances and guidelines rather than to revise regulations. Thus, what is put forth in 21 CFR Part 211 is supplemented with a number of guidances, guidelines and Compliance Policy Guides (4–11). There remain some differences, however, between guidances and guidelines from the Center for Biologics Evaluation and Research (CBER), the Center for Drug Evaluation and Research (CDER), and the Compliance Policy Guides, sometimes leaving a firm’s

cGMP status subject to the interpretation of a field investigator.

Based on the amount of time needed to promulgate a revision of the regulations, it is understandable that it is preferable to work with guidances, guidelines, and compliance policy guides. Current GMPs are supposed to be, as their title indicates, a description of the current manufacturing and control practices that are acceptable for a pharmaceutical company selling products in the United States. Although these cGMPs are not enforced in some foreign countries, an FDA inspection in a foreign country, based on current GMPs, can be the key to importing and marketing a product in the United States.

The FDA is required to inspect a firm every 2 years for compliance to cGMPs. With the advent of programs such as the new drug preapproval inspection program implemented in 1990, inspections may be more frequent and have expanded into areas not previously investigated regularly by the FDA, such as clinical manufacturing. An unsatisfactory inspection can delay approval of new products and lead to further regulatory action by the FDA, such as seizure and injunction, for existing products. The penalties can apply to the individual or both the firm and individuals.

The GMPs as set forth in 21 CFR Part 211 also have been applied to drug substances and clinical products. Guidelines and guidances have been issued to describe the FDA interpretation of 21 CFR Part 211 pertaining to drug substances and the production of investigational drugs and reinforce the agency’s understanding that cGMPs are applicable (12, 13). The FDA has reinforced the connection between registration of drugs and the manufacture of active pharmaceutical ingredients by the issuance of guides to industry (14–16). Recently, the FDA has issued for comment a draft guidance for “Good Manufacturing Practice for the Manufacturing, Processing, and Holding of an Active Pharmaceutical Ingredient” (17). Finalization of these draft cGMP principles is being written into a guideline that is being coordinated through the International Conference on Harmonization of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH) toward publication of a guidance for active pharmaceutical ingredients that will be standardized

^aRevised from Ref. 1.

and followed by manufacturers in the United States, Europe, and Japan (18). As a sidenote, active pharmaceutical ingredients have also been called drug substances and bulk pharmaceutical chemicals.

The “Status of Current Good Manufacturing Practice Regulations for Finished Pharmaceuticals” is as follows:

Section 210.1(a) The regulations set forth in this part and in parts 211 through 226 of this chapter contain the minimum current good manufacturing practice for methods to be used in, and the facilities or controls to be used for, the manufacture, processing, packing, or holding of a drug to assure that such drug meets the requirements of the act as to safety, and has the identity and strength and meets the quality and purity characteristics that it purports or is represented to possess.

(b) The failure to comply with any regulation set forth in this part and in parts 211 through 226 of this chapter in the manufacture, processing, packing, or holding of a drug shall render such drug to be adulterated under section 501(a)(2)(B) of the act and such drug, as well as the person who is responsible for the failure to comply, shall be subject to regulatory action.

The “Applicability of Current Good Manufacturing Practice Regulations for Finished Pharmaceuticals” is as follows:

Section 210.2(a) The regulations in this part and in parts 211 through 226 of this chapter as they may pertain to a drug and in parts 600 through 680 of this chapter as they may pertain to a biological product for human use, shall be considered to supplement, not supersede, each other, unless the regulations explicitly provide otherwise. In the event that it is impossible to comply with all applicable regulations in these parts, the regulations specifically applicable to the drug in question shall supersede the more general.

(b) If a person engages in only some operations subject to the regulations in this part and in parts 211 through 226 and parts 600 through 680 of this chapter, and not in others, that person need only comply with those regulations applicable to the operations in which he or she is engaged.

This article reviews Part 211, Current Good Manufacturing Practice for Finished Pharmaceuticals. Title 21, Parts 600 through 680 for biological products, supplement but do not supersede the regulations in this part, unless the regulations explicitly provide otherwise. The

focus of Good Manufacturing Practice for all products is on a quality control unit that has the responsibility and authority to approve or reject all components, drug product containers, closures, in-process materials, finished product, and production and control documentation. “Quality Control Unit” refers to any person or organizational element designated by the firm to be responsible for the duties relating to quality control. Specific subparts of Part 211 are summarized and described later.

This article is not intended to reproduce the complete GMPs, but certain parts are excerpted for emphasis.

SUBPART A: GENERAL PROVISIONS

This subpart reinforces Part 210, which is an introduction to the more detailed and specific practices described in Part 211. It establishes the scope of GMP and carries forth the definition of terms in Part 210.

SUBPART B: ORGANIZATION AND PERSONNEL

Section 211.22: Responsibilities of Quality Control Unit

(a) There shall be a quality control unit that shall have the responsibility and authority to approve or reject all components, drug product containers, closures, in-process materials, packaging material, labeling, and drug products, and the authority to review production records to assure that no errors have occurred or, if errors have occurred, that they have been fully investigated. The quality control unit shall be responsible for approving or rejecting drug products manufactured, processed, packed, or held under contract by another company.

(b) Adequate laboratory facilities for the testing and approval (or rejection) of components, drug product containers, closures, packaging materials, in-process materials, and drug products shall be available to the quality control unit.

(c) The quality control unit shall have the responsibility for approving or rejecting all procedures or specifications impacting on the identity, strength, quality, and purity of the drug product.

(d) The responsibilities and procedures applicable to the quality control unit shall be in writing; such written procedures shall be followed.

The intent of this subpart is to ensure that there is a group within the organization that can review and judge the acceptability of procedures used to produce pharmaceutical products on an independent basis, as well as judging the products themselves, before they are entered into interstate commerce. The FDA has emphasized separation of the quality control unit from production (organizationally). In addition, the FDA considers the organizational level to which the quality control unit reports very important.

From a legal perspective, the chief executive officer (CEO) or president of a firm is considered the most responsible official and thereby becomes the most liable. Therefore, he is subject to criminal prosecution should the organization be found to violate the Food, Drug and Cosmetic (FDC) Act. One of the most serious infractions is fraud, that is, the intent to mislead the FDA. Hence, it is incumbent on the CEO to have well-qualified personnel in the organization and an organizational structure that reinforces quality.

Section 211.25: Personnel Qualifications

This section emphasizes the training of personnel both in cGMP and in their specific responsibilities with regard to manufacturing, processing, packing or holding of a drug product and functions to provide assurance that the drug product has the safety, identity, strength, quality, and purity that it purports or is represented to possess. This section also requires that there be a sufficient number of qualified personnel.

(a) Each person engaged in the manufacture, processing, packing, or holding of a drug product shall have education, training, and experience, or any combination thereof, to enable that person to perform the assigned functions. Training shall be in the particular operations that the employee performs and in current good manufacturing practice (including the current good manufacturing practice regulations in this chapter and written procedures required by these regulations) as they relate to the employee's functions. Training in current good manufacturing practice shall be conducted by qualified individuals on a continuing basis and with sufficient frequency to assure that employees remain familiar with cGMP requirements applicable to them.

(b) Each person responsible for supervising the manufacture, processing, packing, or holding of a drug product shall have the education, training, and experience, or any combination thereof, to perform assigned functions in such a manner as to provide assurance that the drug product has the safety, identity, strength, quality, and purity that it purports or is represented to possess.

(c) There shall be an adequate number of qualified personnel to perform and supervise the manufacture, processing, packing, or holding of each drug product.

This section makes it clear that the quality control unit is not the only group responsible for the quality of products and conformance with GMP. Because the quality of a product must be "built in," control (at the manufacturing level) of raw materials and process control are important.

SUBPART C: BUILDINGS AND FACILITIES

This section requires that the buildings and facilities are adequate, provide specifically defined areas for certain operations and are designed to prevent mix-ups. Included are design and construction features; lighting; ventilation, air filtration, air heating and cooling; plumbing; sewage and refuse disposal; washing and toilet facilities; sanitation; and maintenance. Lighting, ventilation, air filtration, and air heating and cooling must be adequate. Again, the word adequate is used frequently. This is where an individual investigator's and firm's interpretations can differ.

This section also requires written procedures associated with sanitation and that the facilities should be maintained in a good state of repair. Although it may seem obvious that maintenance should be performed regularly, it can happen that preventative maintenance programs compete with production requirements for attention; however, an in-depth preventative maintenance program should be in place.

SUBPART D: EQUIPMENT

This section addresses equipment design, size, and location, as well as construction, cleaning and maintenance. Similar to the requirements for buildings and facilities, it is necessary to provide appropriate equipment for the manufacture of a product and ensure that the equipment

material of construction is not reactive, additive, or absorptive. In the 1978 version of the GMPs, requirements for equipment cleaning and use logs, as well as written procedures for equipment cleaning and maintenance were added. These requirements aid in the investigation and solution of problems by identifying batches that may also be implicated in a particular problem.

This section also covers the use of automatic, mechanical, or electronic equipment. Additional information relating to compliance with this section can be found in Compliance Policy Guides 7132a.07 (5), 7132a.08 (6), 7132a.11 (8), 7132a.12 (9), and 7132a.15 (10). Compliance Policy Guide 7132a.15 interprets Section 211.68 (b) as requiring maintenance of the program as part of the validation package for computer systems. Reliance on validated computer systems in place of several manual checks has become widely accepted.

SUBPART E: CONTROL OF COMPONENTS AND DRUG PRODUCT CONTAINERS AND CLOSURES

This section relates to the receipt, identification, storage, handling, sampling, testing, and approval or rejection of components and drug product containers and closures, and the requirements for written procedures for each. It also covers the use of approved materials, retesting of approved material, and prevention of use of rejected materials. Although the requirements of this section indicate that each lot be appropriately identified as to its status and that materials in different statuses be stored separately, the implementation of computerized warehouses has made it possible to eliminate status labels and physical separation of quarantined and approved materials. Rejected materials are usually handled separately. These practices are not to imply that a computerized system can be used without appropriate assurance of controls.

The current GMP requirement that materials must be tested or examined for all specifications and released prior to use is in conflict with the philosophy of vendor certification, which is based on a consistent, reliable record of good quality. Only vendors with well-controlled processes and a good record of acceptable batches qualify for such a program. Thus, a material could be put into use based on the quality record of the supplier (vendor), even if testing is only for identification [211.84(d) (2)].

This section also requires the use of oldest approved stock first, retesting of approved stock “as appropriate,” and controls for drug product containers and closures. It

prohibits use of rejected components and drug product containers and closures.

SUBPART F: PRODUCTION AND PROCESS CONTROLS

This section focuses again on the need for written procedures and formal authorization by the quality control unit for any deviation from written procedures. Areas covered are addition of components; calculation of yield; equipment identification; sampling and testing of in-process materials and drug products; time limitations on production; control of microbiological contamination; and reprocessing.

Many drug companies are using electronic means of verifying component names or item codes, receiving and control numbers, weights, or measures, and even the verification of component addition to a batch. There is a range of acceptability on the part of the FDA of electronic means of verification and batch documentation; however, the validation of such systems must be performed to accept electronic means of identification and verification.

The process controls required in this section should be based on process capabilities rather than conforming with a checklist based on the regulations. This would mean that tests not typically used for a particular dosage form may be appropriate, whereas other more commonly used tests may be without any value. This not only depends on the validation of the process but also equipment and process qualification. In addition, the need for microbiological controls can be greatly reduced by knowing whether a product supports microbial growth and whether the environment in the production area is maintained at a sufficiently low bioburden. Clearly, certain products require close attention to the production environment because of the ingredients and the end use.

Many firms use the so-called clean-zone concept, in which the restrictions on personnel entering a production area and the required protective clothing are based on the nature of a product—whether the product is prone to the growth of microbes or whether it is required to be sterile. Even for products not required to be sterile or that are not supportive of microbial growth, this concept controls the production environment through reduction of bioburden.

Reprocessing frequently receives considerable attention from the FDA. Over the years, reprocessing appears to have decreased, not only because of FDA pressures, but also because more products and processes are being validated and better controls are being exercised during production. At times, however, there is the need to reprocess, but it requires authorization of the quality control unit.

For a product covered by a New Drug Application (NDA) or Abbreviated New Drug Application (ANDA), provision for reprocessing must be included in the approved registration document. Although it is not always possible in the filing of an NDA or ANDA to foresee all reasons why a product may need to be reprocessed, a procedure for reprocessing can be evaluated and included in the registration document. If not included in the approved registration document, the regulations require submission of a supplemental application and prior approval in order to market a reprocessed batch.

To some people, batch or lot yield may seem to be more of a business concern rather than a regulatory or technical matter. However, GMPs require that yield tolerances be established and that yields outside of the tolerances be investigated. The need for an investigation is to determine that yields outside of normal limits can be an indication of problems during production that would not be evident with routine testing. A minor deviation may be relatively insignificant and could simply mean that the yield tolerances need to be reevaluated, a procedure that should be followed periodically.

It may seem that the identification of equipment in the processing record is also a superfluous burden. If several pieces of equipment have been shown to be used interchangeably, one might question the reason for this additional documentation; however, when a problem arises, it is necessary to know exactly which equipment was used. It may be possible to trace this back by reviewing equipment cleaning and use logs, but the investigation is simplified by having this information in the batch record. Recording variable batch information concerning the equipment, such as tablet compressing speeds, is also necessary.

SUBPART G: PACKAGING AND LABELING CONTROLS

This subpart covers one of the aspects of pharmaceutical production that has received much attention because of recalls, including an increase in recalls related to labeling errors or product mix-ups associated with the packaging and labeling operation. Specific requirements identified in this section recently include the following.

Section 211.122: Materials Examination and Usage Criteria

- (f) Use of gang-printed labeling for different drug products, or different strengths or net contents of the

same drug product, is prohibited unless the labeling from gang-printed sheets is adequately differentiated by size, shape, or color.

(g) If cut labeling is used, packaging, and labeling operations shall include one of the following special control procedures:

1. Dedication of labeling and packaging lines to each different strength of each different drug product;
2. Use of appropriate electronic or electromechanical equipment to conduct a 100% examination for correct labeling during or after completion of finishing operations; or
3. Use of visual inspection to conduct a 100% examination for correct labeling during or after completion of finishing operations for hand-applied labeling. Such examination shall be performed by one person and independently verified by a second person.

(h) Printing devices on, or associated with, manufacturing lines used to imprint labeling upon the drug product unit label or case shall be monitored to assure that all imprinting conforms to the print specified in the batch production record.

Section 211.125: Labeling Issuance

Section 211.125 has been amended by revising paragraph (c) to read as follows:

(c) Procedures shall be utilized to reconcile the quantities of labeling issued, used and returned, and shall require evaluation of discrepancies found between the quantity of drug product finished and the quantity of labeling issued when such discrepancies are outside narrow preset limits based on historical operating data. Such discrepancies shall be investigated in accordance with Section 211.192. Label reconciliation is waived for cut or roll labeling if a 100% examination for correct labeling is performed in accordance with Section 211.122(g)(2).

Section 211.130: Packaging and Labeling Operations

Section 211.130 has been amended by redesignating paragraphs (b), (c), and (d) as paragraphs (c), (d), and (e), respectively, and by adding a new paragraph (b) to read as follows:

(b) Identification and handling of filled drug product containers that are set aside and held in unlabeled condition for future labeling operations to preclude mislabeling of individual containers, lots, or portions of lots. Identification need not be applied to each individual container but shall be sufficient to determine name, strength, quantity of contents, and lot or control number of each container.

These requirements reflect an increased use of electronic means to ensure correct labeling and tight controls on the practice of filling containers that will be labeled at a later date. A time-consuming operation required in the current GMPs is associated with the reconciliation of labels. The recalls and associated investigations demonstrate that unless 100% accountability can be achieved in the reconciliation process, there will not be an effective means of ensuring correct labeling.

Section 211.132 was revised on February 2, 1989, to describe tamper-resistant packaging and labeling requirements for over-the-counter (OTC) human drug products. Compliance Policy Guide 7132a.17 (11) was issued in 1992 to describe the standardized tamper-resistant packaging requirements. This section also covers information concerning requests for packaging and labeling exemptions. It allows changes in packaging and labeling to comply with the requirements for OTC products subject to approved NDAs to be implemented prior to FDA approval as provided for in Section 314.70(c). Manufacturing changes to provide for sealed capsules require prior FDA approval under Section 314.70(b).

Section 211.132 states that none of the requirements for “special packaging” (child-resistant packaging), as defined in Section 310.3 (1) and required under the Poison Prevention Packaging Act of 1970, are affected.

Subpart G also covers drug product inspection and expiration dating. The expiration date that is required in Section 211.137 relates to stability studies performed on the drug product described in 21 CFR 211.166. It requires that expiration dates be related to storage conditions stated on the product labeling.

Furthermore, the programs established are to use stability-indicating methods, under controlled conditions, in the marketed container–closure system and on an adequate number of batches to determine the appropriate expiration date. The FDA has issued guidelines on stability testing which outline in more detail the requirement to establish a stability program to determine and support the expiration date of a product (4a, 4b, 7). A new draft guidance for stability testing was published by the FDA in 1998 (19), and discussions with comments to finalize this guidance are still continuing.

SUBPART H: HOLDING AND DISTRIBUTION

This section covers warehousing and distribution and the procedures required for the quarantine of drug products before release by the quality control unit, storage of drug products under appropriate conditions, procedures to ensure use of the oldest approved stock first, and a system for documenting the distribution of each lot of drug product. This is another area where computerized systems are being used extensively. During inspections, the FDA review includes evaluation of the validation of any computerized systems and controls.

SUBPART I: LABORATORY CONTROLS

This entire section refers to the requirements covering the testing of drug products and their components prior to release for distribution. It also covers stability testing and special testing, including testing for penicillin, if a reasonable possibility exists that a nonpenicillin drug product has been exposed to cross-contamination with penicillin and laboratory animals. Additional information can be found in the Good Laboratory Practices, 21 CFR 58.

Reserve samples are required to be maintained for active ingredients and drug products. These specific requirements are elucidated in 211.170. The section on reserve samples also requires that a visual inspection of reserve samples of drug products be conducted at least once a year for evidence of deterioration.

Fundamental to the testing requirements is the need for validated methods with established and documented accuracy, sensitivity, specificity, and reproducibility. It is also necessary to have meaningful sampling and testing plans that meet statistical quality control criteria. Judgments made with regard to sampling procedures should be based on the quality of the process control or the reliability of the vendor who supplies a raw material, drug substance, or packaging component.

SUBPART J: RECORDS AND REPORTS

This section details the records and reports required to be maintained for pharmaceutical drug products, their components, and the equipment used in the processing of a drug product. Through these records, the entire history

of a batch can be traced. The records cover equipment cleaning and use logs; component, container, closure, and labeling records; master production and control records and production record review; laboratory records; distribution records; and complaint files. Because this amount of recordkeeping can be voluminous, Section 211.180(d) allows for microfilm, microfiche, or other accurate reproductions of the original records for storage. Many firms are using the electronic generation of batch and analytical records. It is important to be able to retrieve all of the above records easily during an FDA inspection. Electronic methods must be supplemented with proper procedures to ensure that the records do not deteriorate over a period of time and can be retrieved when the computer systems used to generate the records have been revised or replaced.

This section also requires a master production and control record for each product, from which the batch production and control records are generated. These records must include complete instructions concerning the manufacture of a batch and precautions to be followed. Prior to the commercial distribution of a drug product into interstate commerce, all executed production and control records must be reviewed. If there is a discrepancy or a failure of any batch or any of its components to meet specifications, there must be an investigation and a written report of the findings. The investigation are to extend to other batches of the same or other drug products that may have been associated with the out of specification batch or discrepancy.

Another part of this section covers complaint files, which are reviewed regularly during FDA inspections. In fact, a complaint file review may be the sole reason for an inspection if the FDA receives a complaint directly from a pharmacist, which may be a cause for concern. Sometimes the FDA will visit a firm to follow up on a complaint, even though the firm may not have been informed by the complainant. In the event that a complaint is received by a firm, it should be evaluated and a response sent to the complainant. It may be necessary also to conduct an investigation and prompt further action regarding the product or batch in the marketplace.

SUBPART K: RETURNED AND SALVAGED DRUG PRODUCTS

This section requires that extensive records be maintained on returned drug products including ultimate disposition.

Again, if the reason that a drug product is returned implicates other batches, an investigation is to be conducted in accordance with 211.192. Drug product salvaging is not allowed for drug products that have been subjected to improper storage conditions. If there is a question as to whether drug products have been subjected to such conditions, they may be salvaged only if there is evidence from laboratory tests that all applicable standards of identity, strength, quality, and purity have been met. In addition, evidence is required from the inspection of the premises that the drug products and associated packaging were not subjected to improper storage conditions as a result of a disaster or accident. Understandably, the value of the material to be salvaged is taken into consideration when such rigorous requirements exist for salvaging.

CONCLUSION

Compliance with cGMP requires that responsible employees in a firm be knowledgeable about the practices that other firms follow in order to comply. FDA investigators visit many firms and find a broad picture of current manufacturing and control practices. Thus, Current Good Manufacturing Practices are “state of the art,” constantly changing. To be in regulatory compliance, a firm must review their procedures and systems regularly and revise them as necessary.

GOOD LABORATORY PRACTICE (GLP)—AN OVERVIEW

Nigel J. Dent

Country Consultancy Ltd., Northamptonshire, United Kingdom

OVERVIEW

The Good Laboratory Practice Guidelines (GLP) have been in existence for nonclinical safety studies since 1976 (1–8). They have progressed through various transitional phases to become guidelines in some countries and regulatory/statutory instruments in others.

The current document is the Organisation for Economic Co-operation and Development (OECD) Principles of GLP (9) and is currently accepted as the industry standard. This was reviewed and published in January 1997 (10, 11) but must be used in conjunction with the appropriate Scientific Guidelines for the scientific side of the study, i.e., the OECD Toxicology Guidelines etc. (12). This sets out to cover all nonclinical safety studies and gives guidance as to how these studies should be conducted in conjunction with the appropriate regulatory toxicology guidelines and, on that basis, when encompassed in the various Directives of the European Union (EU) (13) or in other Memorandum of Understanding, allow data generated under this program to be mutually accepted by other OECD countries. One must not forget, however, the other equally important Guidelines and Regulations of other countries, such as those of the U.S. Food and Drug Administration (FDA) (14) and the U.S. Environmental Protection Agency (EPA) (15–20), and similar organizations in Japan (21). All have basically similar rules and, being members of the OECD, data generated to the OECD principles will generally be accepted in the United States and Japan. The EPA regulations used to be quite different and were applied to agrochemical and pesticide products. However, having been revised recently, they have been brought in line with the documents of other agencies.

The guidelines themselves, with the exception of those in countries where they are featured as regulations, are, as stated, guidelines to the conduct of the study and aim to cover compliance with the GLP principles but in no way do they dictate how the science will be performed.

It must be remembered that compliance is monitored by adherence to GLP, whereas the regulatory authority and the receiving authority of the dossier when submitted for the application of a marketing permit or similar document review the science.

OBJECTIVE OF THE GUIDELINES

The general objective of the guidelines originates in the very early 1970s, when one pharmaceutical company in particular and a contract research organization (CRO) generated data that, when submitted to the FDA, gave them cause for concern in the accuracy of the data presented and, in certain instances, the honesty of the submission.

At that time, a full review of companies and institutions conducting nonclinical safety studies (toxicology) was undertaken by the FDA (22) and although, in general, the industry was found to be credible, one company (Industrial Biotest) was found to be generating extremely poor-quality data, in many instances, in a fraudulent manner. This, therefore, caused the FDA to put together and implement the GLPs (23, 24).

Over the next 10 years, many countries introduced similar good-practices guidelines. The EU (25) in general produced its guidelines and eventually, despite the fact that the world was operating according to similar principles, a standard document was produced by the OECD in the early 1980s and became the industry standard. The reason this was of benefit to the whole industry was because this now precluded the fact that every submitting company would have to be inspected by each relevant monitoring authority and, when implemented into several directives and legal statutes (26, 27) within the OECD (particularly in the United Kingdom) (28), this allowed data generated by one company to be accepted by several receiving authorities without further inspection.

The objective of the GLPs is to ensure that a standard approach is undertaken covering traceability and accountability and, while still allowing freedom for the scientists, to impose certain restrictions on the generation of data and the experimental work.

It must be remembered that GLP is merely common sense in a formal environment. The key phrases that are currently seen in a GLP environment include good documentation, good training, maintenance and calibration of all equipment, the archiving and storing of data in a formal and retrievable manner, and the use of high-quality, validated equipment and accredited test systems (animals).

This in general is merely good science, and the GLPs have further enhanced this by the addition of an independent Quality Assurance Unit (QAU) and a study director/principal investigator who jointly controls and oversees the project and involves the management in putting together adequate resources and assuming overall responsibility for the study.

This can be seen as good science, with several slight enhancements. The details of these individual subjects are addressed later in this article.

WHO DOES IT AFFECT?

Any company or institution performing nonclinical safety studies for the submission of data for a new chemical entity; a new biological, immunological, pesticide, veterinary or agrochemical product; or, for that matter, a similar product that will eventually appear in the marketplace and be consumed by the general public must adhere to GLP in the conduct of their nonclinical safety study experimentation.

Within a company, every person from senior management to the junior technician is bound by these GLPs and must exhibit clear understanding and training in these practices.

To ensure that the practices are followed, a regulatory inspection takes place on a 2-year basis in most countries, and the objective of this is to review, as an independent group, how these good practices are being followed. Certification or a guarantee that the company is operating according to these standards is the benchmark standard. This is also addressed later in this article.

As we move into the twenty-first century, it is quite apparent that the industry will shrink as mergers and acquisitions (29–33) take place, and, with this, the emergence of the now familiar CRO will become ever more popular in the conduct of nonclinical safety studies. It is, therefore, very important that, in this area, the sponsor has the assurance that these facilities are operating not only to the highest standard of science but also in compliance with GLP and that, as a subcontractor, the data they generate will be equally accepted as if the data were generated by the company itself.

WHY HAVE IT?

In general terms, for companies conducting nonclinical safety studies (34), it is, a regulatory requirement, and without this certificate or certification of compliance, data

will generally not be accepted by the receiving/regulatory authorities.

However, one should not embark on the process of obtaining or working to GLP with this sole aim in mind. It should be used as an ongoing improving and quality standard for the laboratory.

In fact, it is the author's experience over the past 5 years, that many companies have gone far beyond the requirements of GLP compliance (35) and that the overall concept of good scientific design and good science has been superseded by the desire merely to obtain compliance. It is quite often seen that an extremely poor quality scientific study has been conducted in complete compliance with GLP. It has been seen on several occasions in a laboratory, for example, where the refrigerator has been located far from its permitted limits; where the temperature has been diligently recorded, signed, and dated as required by GLP, but where no attempt has been made to either document the excursions outside the accepted range or to rectify the problem. The operative was merely under the impression that as long as temperature is recorded, this is GLP despite the damage that excursions outside the temperature range may have caused to any investigational product stored in the refrigerator.

Over the years, those scientists who have worked according to the principles of GLP now readily admit without any prompting that they are unsure how they conducted scientific studies before the advent of these good practices. The ability to reconstruct studies, to work to a standard format across several differing laboratories or countries, and to be able to prove beyond reasonable doubt that these were the values obtained and the results submitted.

Certainly, data with a GLP compliance statement are being accepted more readily by the receiving authorities, which has led to fewer repeated studies. This, in turn, is helping to achieve the aim of all scientists in reducing the use of animals.

From a company's point of view, working according to the principles of GLP shows that it has an attitude that is both ethical and moral to the production of scientific data with products that will eventually enter the human food chain or be of benefit to mankind.

HOW IS IT ENFORCED?

In the OECD countries, for at least 14 years, an Inspectorate has been set up, varying in inspector numbers from several hundred in the United States to one or two in

countries not conducting a great deal of scientific nonclinical research. All countries, however, have a regulatory group that, in some instances, also acts as the receiving authority for the review of data, and reports to the GLP Monitoring Authority. This regulatory group visits on a 2-year basis or, in Germany, a 4-year basis, those companies that have claimed compliance and will then be on a rolling program of review (36).

Unlike its role in many areas of regulatory compliance, it is still the responsibility of the sponsoring company to claim compliance from the Monitoring Authority. This claim is made for a particular company, laboratory, and/or series of tests. From the date of compliance when a letter is written to the Monitoring Authority, data generated from then are assumed by that company to be in compliance with GLP. This claim is then verified in a visit from the regulatory inspector. The inspection may be performed by one or two persons for 1 to 5 days. At the end of the inspection, an exit meeting is held, and the company is usually given an indication of its performance. Noncompliance points are noted in writing and discussed, and a report is then prepared. In view of the findings, three levels of compliance can be obtained:

1. Sufficient deviations have been seen to question the integrity of the data and, therefore, a complete rejection of the claim of compliance is made, with a revisit necessary.
2. Minor points of compliance have been seen that can be handled in a specified period in which case, the laboratory is placed under the category, of pending compliance.
3. Very minor points of compliance have been seen, which, when addressed in writing by the management in a 1-month period with supportive paperwork, etc., lead to the company being given a Statement of Compliance, a Certificate of Compliance, or an indication that the laboratory is in compliance. It depends on the specific country whether a Certificate of Compliance is given. If a certificate is given, it generally states that on the particular day that the inspection took place, the laboratory was found to be in compliance with the OECD Principles of GLP. Also, the address of the facility is given as well as a listing of areas in which compliance has been confirmed. This could be stated as *analytical support facilities, acute toxicology, mutagenicity*, or similar designations.

Naturally, the benchmark standard is either the OECD Guidelines or similar standards in Japan or the United States. The Inspectorate carries out inspections against these documents. It could be said that often it is merely a

review of the procedure and an opinion of compliance given by the inspector versus the interpretation of the individual conducting the experimental work. To try to overcome this criticism and to ensure that all inspectors work according to a standard format, over the past 4 years, the OECD has instituted a series of mutual joint visits (MJVs) (37).

The process of an MJV is that a company is inspected by its local inspector and that the inspector is accompanied by inspectors from two other countries as observers. At the conclusion of the inspection, the company is given their findings by its local inspector and, outside that meeting, a review of the performance of the inspector with positive and negative points is given by the two observing inspectors. To ensure continuity, one of these three inspectors would then be on the next MJV.

In the past, Memorandums of Understanding (MoUs) (38) have been instituted between certain major countries, such as Japan and the UK, the United States and Japan or Canada, etc. However, these have generally fallen into nonuse for a variety of reasons, especially in Europe, where it is now, or has been for some time, not possible for a country to negotiate directly with another country. Brussels, however, being the center of the European Community, has to carry out that discussion with a proposed partner in another country. As such, at the time of producing this overview, very few MoUs are currently in force.

WHAT IS GLP?

As noted in the Overview, GLP is a series of guidelines that cover the conduct and data production for nonclinical safety studies.

The OECD covers a series of activities and personnel. Responsibilities, training, quality assurance (QA), standard operating procedures (SOPs), study plans and study reports, data production and recording, equipment maintenance and calibration, computers and validation, test systems and test substances, and archiving are the primary areas covered by the GLPs.

A very brief overview of each of these areas is given hereafter.

Responsibilities

The prime players in a GLP scenario would be the management, the sponsor, the study director, the principal investigator, and the QA.

In a hierarchical structure, management would be totally responsible for the conduct of the work and for the

assurance that resources have been made available and that an active role is played by these people in overseeing the conduct of scientific research.

The sponsor is the company that places a contract with a CRO or requests from within a company that work in another department be undertaken. The sponsor is the person who is supplying the money and the request for the work.

The study director is the prime player and is ultimately responsible for the production of the study plan, the conduct of the study, and the overseeing or production of the final report. Naturally, a large amount of delegation may take place; however, this must always be in writing, and the overall responsibility for the conduct of the study; the daily contact with the study staff; the prevention of recording of problems and the assurance that the study has been conducted in line with the study plan, the GLP, and the scientific guidelines solely belongs to this individual.

The Principal Investigator is the next in line of responsibility after the Study Director in a multisite study. For example, they could be the person seen in a field study situation where the crop-spraying, for example, may be undertaken at a place remote from the GLP designated site where the study director works. The principal investigator is therefore the person responsible initially for that portion of the work, although under the direct control of the study director. It may also be that, within a company, work is subcontracted to the Analytical Department, for example, for the analysis of formulated material. The person responsible for this particular aspect of the scientific work is the principal investigator, who is involved in the study plan and responsible to the study director. Another typical scenario is work conducted in a CRO under the control of the study director, where samples of plasma are taken for toxicokinetics, for example, and these samples analyzed by the sponsor. The sponsor's analyst, therefore, may well be designated the principal investigator.

Quality assurance

This is an independent group that does not become involved in the conduct of the study but merely reviews the data, experimental work, and documents produced to ensure compliance with the SOPs, the study plans, and GLP. Other activities such as training and assistance in interpreting GLPs, etc., may be the responsibility of the QAU. (For more information, see the following section in this article or Section II, 1.4 pp. 17–19 of the OECD GLPs.)

Training and recording

It is the responsibility of the management to ensure that training takes place and the responsibility of the Study

Director to assure that the individuals conducting the work are adequately trained and have adequate records. At a minimum, there must be a CV, a training record, and a very clear job description. Specifically, with regard to a study director, there must be explicit details of how the study director position can be met and the responsibilities of that individual in carrying out the relevant duties.

There should be procedures detailing how the training will take place; recording of the training must be made on a regular basis, the records must be stored in archives and regularly updated, and a complete and historical review of the trainee's activities, previous training, and ability to conduct the work according to GLP must be documented. (See the OECD Principles, Section I, 2a–d.)

Quality Assurance

This function, as has already been stated, is an independent review. The responsibilities here start with a review of the study plan and continue through the review of the study in the in-life phase, data audits, and the final study report audit.

In addition to these, systems audits and process audits can be undertaken.

The aim of QA is to assure the management that compliance with GLP is maintained throughout the entire study, that the data integrity is maintained, and that compliance with the SOPs and the study plan is adhered to by all experimental study staff. The study audit is a specific audit of the study in direct relation to the study plan. A systems audit, however, rather than proceeding in a vertical line, takes a horizontal line across all studies and would include such tasks as archiving, training, SOPs, general computer validation, animal house operation, and management activities. These are but a few areas that would constitute a systems audit but, hopefully, gives an idea of the type of activities across studies that would be audited.

Process audits, on the other hand, have specifically been addressed in the revised 1997 GLPs, and these are basically aimed at auditing short-term studies of a repetitive nature, generally undertaken by similar teams of people. Here, that the system is working and that parts of the process are reviewed over a quoted period in the QA SOP are assured. The aim is to ensure that all critical aspects of this process are reviewed through different studies over a period of time. This, then, does not necessitate QA review of all short-term studies on every occasion, nor does it require the review of such areas as analytical analysis on a batch-by-batch basis or the analysis of hematology or biochemistry samples each time these come up for analysis.

QA itself is required to produce SOPs that clearly detail operation, method of selection of critical phases, and studies and to report its results to the management.

After every audit, a report is produced that is then discussed with the study director and circulated to the management with the overall agreement from the study director relating to the audit findings and their explanation of the resolution. (For an in-depth review of QA, see Principles of GLP, Section II, 2.1–2.2, p. 20.)

Standard Operating Procedures (SOPs)

These generally have been likened to a complete documented history of the entire aspect of conducting nonsafety studies. Any activity needs to be described in one of these documents. There may be a compilation of activities, or they may address single items such as the calibration and use of an electronic balance. They must be produced by the individual most familiar with the task, agreed on by the management, and countersigned by a person senior to the author.

Once produced, SOPs must be reviewed on a regular basis, (approximately every 2 years) and any changes to these procedures must be made in writing, with the agreement of all parties and circulated to each owner or user of the SOP. The SOP itself must be filed in the archive and additional copies produced. An SOP management system must be set up, whereby a responsible person knows the whereabouts of all SOPs and can retrieve and replace them with amended or superseded revisions and can make sure that they are reviewed regularly and disposed of when no longer required.

The SOP must appear immediately in the area adjacent to the workplace to be readily available to all persons. Frequently, SOPs are the basis of training, and most companies now have SOP-based training schemes. The content and receipt of the SOP should be acknowledged immediately on receipt and a training program set up whereby confirmation of the understanding and the ability to perform the duties stated in the SOP is documented in the appropriate training record.

SOPs should be adequately controlled to prevent unauthorized photocopying, which may lead to the possibilities of a superseded copy not being administered to the known recipients. Someone making an illegal photocopy would not be on the distribution list and, therefore, would not always receive updated versions, with the possibility that an outdated method could be used.

The requirement for archiving historical copies is one of the key attributes of GLP in that traceability can be seen as originating at the archive. The dates and historical

record of the SOPs can prove irrevocably that a particular action was the method in use at the time.

SOPs can be paper-based or electronic. The trend toward electronic record-keeping is becoming more common in laboratories. The only requirement made by the inspectorate is that accurate, controlled copies are available on the electronic media and that prevention of copying or unauthorized changing are built into the SOP system. (See GLP Principles Section II, 7, p. 24.)

Study Plans and Reports

Before any study can be undertaken satisfactorily, a study plan must be produced. The study plan is merely an indication of all of the activities that will take place, resources required, time frames, and objectives. The study plan can be likened to a road map that, when given to all the participants, will allow them to start at the beginning and to proceed through the various mazes to the final completion point indicated by the study report. The one golden rule in GLP is one study plan, one study director, and one report.

The study report itself is a mirror image of all the headings in the study plan and serves to confirm that the objectives of the study have been met and that the results and discussions of the data presented give an indication of the outcome of the particular experimental work.

Both the study plan and the report are audited by QA, and each study plan and report are generally determined by the company's format.

Typical headings must be given in both documents. (These can be found in Section II, 8.1–8.3, pp. 25–27 and 9.1–9.2, p. 28, of the OECD Principles of GLP.)

Data

Raw data, or source data, are generally considered the first records made, either electronically in computer-readable form, or records created the first time that the “pen hits the paper.”

These should be original signed and dated recordings that may be on any type of media. Cases in which media such as heat-sensitive paper contain the result, should be photocopied in the event of deterioration over a time.

Electronic data can be regarded as the disk, CD-ROM, or similar media provided that this material, when reintroduced to the computer and the software, can generate the images stored on the disk or electronic media in a 100% readable form.

There are many types of electronic media, machines, and source data or raw data within the toxicological environment. However, ironically, the most common storage media and the most common raw data are paper.

Paper and its storage partner, microfilm, have been around for many years, and their stability and reproducibility are well known. Other electronic media, however, do not have the same capability of reproduction known over a long period, and, thus, most industries and companies prefer paper.

In regard to the data they should be recorded promptly, legibly, and signed and dated, and any corrections should be made in a format to allow the original record to be seen, the change described and justified where applicable, and the change signed and dated by the individual making the revision. This procedure, whether on paper or via computer, should have the same standards. With use of the computer, an audit trail is necessary to identify the change and the person making it, along with the reason.

Equipment

As can be imagined, equipment in a toxicological study may be varied, simple, or complex. As such, it is difficult to describe each individual type of equipment in this limited space.

GLP requires that equipment be maintained, calibrated, and generally demonstrated as fit for use.

Equipment such as high-pressure liquid chromatography (HPLC) should have system-suitability checks, installation qualifications, and operational qualifications performed at a minimum.

Other equipment such as centrifuges and balances should be maintained and calibrated and, with regard to the latter, regular checks should be made with known, standardized, regularly calibrated weights. These should be placed on the balance with a frequency to guarantee that data from the machine are accurate. Even if the balance is an electronic calibrating balance, regular manual check weights should be applied.

Each piece of equipment should have a log book that gives a historical record of its use, breakdown, repair, and service. Generally, it is acceptable that these log books be placed by the equipment generating critical data to be presented in the final report.

All equipment should be clearly identified as to the time that it started producing raw data for experimental use and, when no longer required, the equipment should be removed from the laboratory or suitably labeled “not for GLP use.”

The calibration and validation of equipment have been addressed extensively but, equipment that can be shown as “fit for use,” within the GLP environment is generally acceptable to most regulatory inspectors. (For additional information on the GLP requirements for equipment, see Principles, Section II, 4, p. 22.)

Computers

Over the past few years, computers have played a very important role in many aspects of toxicology. The general trend in the industry and particularly from the Inspectorate is to ensure that they are fully validated.

Validation, however, means different things to different people. Some companies and their Information Technology Group (ITG) will dismantle the computer and its software components, reconfigure them, test them, and then reinstall them. Others will take a more realistic approach and work on the basis that the computer was brought in for a specific task and, is considered validated provided that task is completed with the aid of the computer in a reproducible and acceptable manner.

However, in the most simplistic form, validation could be covered by “evidence that the computer will perform the task for which it was purchased and, more importantly, continue to perform that task for the foreseeable future.” In other words, as with other equipment, is the computer fit for purpose?

Several documents have been written from a regulatory standpoint, the most useful being Monograph 10 of the OECD Principles, *Application of GLP to Computer Systems* (39). Many books are available and vary in detail and content to cover everything that one would wish to know about computers, but were afraid to ask, down to the simple documentation giving the essentials for validation and providing a disk with the SOPs to comply with GLP! Several examples are listed in the References (40–42).

The prime concern of the Inspectorate is that the user responsible for performing the validation and producing the report is in control of the equipment and can ensure and prove the integrity of the data when entered into the computer and regenerated in some other form.

It is generally accepted in the industry that acceptance testing is perfectly satisfactory for most computers and assures that the computer, when installed on company premises, will perform the function for which it was purchased. However, each computer must be viewed in the role it will play in the company and suitable testing must be conducted to ensure that the data and integrity are of the highest quality and that total control over output is maintained.

As with all equipment, computer maintenance and calibration records are of paramount importance. If in-house software programs are produced, they are tested and validated, and the source code is made available. One of the key elements required in the computer record-keeping is that of change control and password protection and training. (See GLP Principles Section II, 7(b), p. 25.)

One very important rule is that *the electronic signatures rule* (43), and it must be observed when data are signed off electronically. This FDA requirement became effective August 20th, 1997, and covers all data for which signatures are made electronically and requires that the FDA is officially notified.

Test Systems

This really is a slightly complex name for what is generally considered the animal subject. Test system, however, has been utilized because in many instances in toxicology, GLP now applies to such subjects as ground water, soil, insects such as earthworms and honey bees, and microorganisms such as daphnia and, therefore, the use of the word *animal* is not always applicable.

The main criteria are that the origin of the test system is known with its breeding history, where applicable, that these are purchased from well-known and, if possible, accredited suppliers, and that the quarantine period is observed to ensure that test systems are of high quality and fit for use.

Care, husbandry, intermediate sacrifice if the test system is found to be “in extremis,” and humane sacrifice before necropsy are essentials for the test system. Separate housing among species and experimentation is critical, and all aspects of manipulation of the animal from clinical observations, dosing, and special tests such as electrocardiogram (ECG) need to be well documented and outlined in SOPs.

Animal husbandry itself, the animal room, and the animal room diary giving an indication of exactly what occurred in the room and to the animal are essential items of documentation. Unique identification is also of paramount importance with the animals, cages, and the location of the cages.

Full and documented history of heating and ventilation are required and, in barrier-maintained rooms, signed and dated records of positive to negative pressures are to be kept. These records should also reference any malfunction and its rectification. Furthermore, *excursions outside the permitted range* must be documented, and the effect on the study and data integrity must be identified and addressed by the study director in the final report. (Additional information is available in the GLP Principles, Section, II, 3.2, p. 21.)

Test Substance

In most instances, the test substance can be the new chemical entity (NCE) or an existing product; a comparator, pharmaceutical, veterinary, or agrochemical product; or even a device. Knowledge of the composition,

characterization, stability, and other physiochemical properties is essential. Stability, however, may be determined as the short-term studies progress, with the proviso that the overall stability is known, along with full characterization, by the time long-term toxicity studies are carried out. Stability testing may well be carried out in parallel as long as the stability of the active ingredient and formulated product is known sufficiently to allow for control of the dosing to be done within the period of stability known at that time.

One of the key elements of test substance control is accountability. A record of the amount received for toxicity testing should be accurately recorded, and 100% accountability of that product throughout the life of the testing is an essential element of GLP.

Again, formulation of the product is required to be covered in detail, and, in many companies, the elements of GLP are the benchmark standards when dealing with test substance. Use of the test substance in the animal facility, the maintenance of homogeneity of suspensions, the mixing of the product in feed, and the testing of the product are all essential. This is one particular area in which within the toxicology testing area, support functions such as analytical studies then come under GLP. These functions will be required to test formulations and feedstuffs, etc. to ensure that the correct amount of the active ingredient is present as determined by the study plan for the various dosing groups. This requires that a validated method be available before any work is carried out, with the ability to analyze samples of the formulated product or plasma samples for toxicokinetics as the study progresses.

It is required that a reserve or retention sample of the active ingredient is retained. This should be retained for as long as it affords reasonable testing and within the expiry period determined by the analytical facility. It is also required that a retention sample be retained for studies that are not considered to be short term. This is one particular area in which revision of the GLPs is sometime not well-thought through. Originally, it had been stated that reserve samples should be taken for studies exceeding 4 weeks. This was subsequently revised to specify “studies that are not considered to be short-term.” The glossary in the GLPs defines a short-term study as “a study of short duration with repetitive processes.” This, one must admit, does not give a lot of guidance!

(See additional information on systems in GLP Section II, 3.3, p. 21 and 6.1–6.2, p. 23.)

Archives

Having addressed all the various aspects of the study, one can see that much documentation, tissues, slides, and wax

blocks could well be accumulating. The requirement is to store this material for “a period of time.” Again, very little guidance is given in the GLP, and one is referred to the national guidelines for the storage of data. However, it is of great importance that this material is maintained in good condition in a retrievable format for at least 15 years for or 2 years past the availability of “the product,” whichever is longer.

Generally, companies themselves are maintaining that material for far longer, or for 2 years past the availability of the product.

All the material must be retained in a secure location for easy access, under the responsibility of a management-designated archivist and deputy. The security aspect of the archive should preclude damage from outside sources, fire, water, rodents, etc.

The entire aspect of archiving is basically one of common sense, and guidance on how to archive these materials can be obtained from government agencies that store personnel records or from libraries. [Additional information on archiving is available in GLPs under Section II, 3.4, p. 22 and 10, p. 29 and in the British Standard for Archiving (44).]

HOW CAN COMPLIANCE BE MAINTAINED WITHIN A FACILITY?

Compliance, having been granted after an inspection, should be monitored on a daily basis. However, it is the author's opinion that many companies standards of compliance relax after the initial certificate has been granted only to find that, 2 years later, for example, an enormous rush 1 month before an announced inspection is required to generate the appropriate documentation and to update the system. It is suggested that QC reviews be carried out on a regular basis to ensure that points likely to detract from the overall compliance are reviewed regularly and that project meetings be held where QA is invited to give a précis of the regular points seen during audits so that these can be addressed and rationalized.

Training and retraining, along with an awareness of the requirement to comply with GLP, are of immense importance. New equipment, major SOP revisions, and transfer of technicians or scientists among departments are always good signs that additional training be carried out. It must be remembered that GLP is team work. It is no good considering that there are the scientists and technicians on the one hand and, QA on the other. There is also no point in considering that whatever

happens and however little QC is carried out, QA will discover all the mistakes in the final report and review. Remember, it is not QA's problem; that department's role is to ensure that compliance has been maintained; QC and data-checking are the responsibilities of every member of the staff team.

Improvement targets should be set in line with quality-control manuals used in other accreditation systems. It is always a good point to review internally and on a regular basis: 1) problems that have been encountered in experimentation; 2) audit findings; 3) ways to improve work by looking at new systems and reviewing SOPs to ensure that these are current; and 4) and areas where improvements can be made.

An example can be taken from the accreditation systems (45), in which, in addition to QA audits, departments become involved in self-inspection. Each department can identify a QA representative whose daily responsibility is to review compliance issues, to look at the overall quality policy of the company, and to ensure that between QA audits, self-inspection is performed and that a departmental review is made of these findings with action points and a time plan identified.

The primary impetus for the maintenance of compliance, however, is the regular external inspection by the Inspectorate. In addition, it is now becoming frequent for independent consultants to be brought in to do preregulatory inspections. Whichever way one views the system, whether through consultation or by assigning a department to perform inspections in one area and to conduct audits in another, the regular review of compliance should be maintained.

When using CROs, the whole aspect of auditing takes on a different light. Here, subcontracting is usually performed because of internal pressures, shortage of space, or lack of in-house expertise. Dealing with CROs is no different than setting up an in-house GLP system. The CRO should be regarded as an extension of the facility in which the sponsor is conducting its own research.

PITFALLS AND BENEFITS

In conclusion, it is worthwhile to address the pitfalls and benefits of operating according to the principles of GLP.

A pitfall could be seen as a restriction on the scientist against performing free research. It could also be seen as an intrusion by an independent body looking at why problems occur and at the sorts of problems that occur and carrying out regular reviews with senior management about these problems. Costs will increase because of time pressures

and the necessity of involving third-party reviews. The recording of data will now be subject to more QC, more required approvals, extra costs, and, generally, more data presented. Time must be taken to write and review SOPs. This in itself can be a very costly exercise; the author knows of one company that, having spent more than 6 months writing its SOPs, classed them as capital pieces of equipment and put a value of \$5500 on that volume.

Other companies and personnel may encounter similar pitfalls. The list is not intended to be exhaustive but merely to indicate areas in which additional time, money, and resources will be allocated. However, on the positive side, benefits can be seen immediately.

In talking to many people who have operated under the GLP system for the past 20 years, it is generally heard that the system allows for a better standard of research, less repeated work, the ability to have full accountability and traceability of everything within the experimental phase, and the knowledge that all documentation produced at the end of the study is now safe and secure in the archive and can be readily accessed for regulatory review or inspection.

Fewer studies are being repeated, and, therefore, the immediate benefit is the lowering of subject usage.

The fact that data, when generated with a certificate or a compliance statement, will now be accepted by all OECD member countries means that once the study is completed and the regulatory submission made, the time for acceptance several countries (if submissions are made in a multistate procedure) will be reduced dramatically.

Finally, it is considered that the initial bureaucratic straitjacket of GLP when thrust on the international research community in 1976 has rapidly turned full circle and now is seen as the quality standard to which all companies in all countries want to aspire.

From that point of view, all nonclinical safety studies, when conducted according to the principles of GLP and adequately addressing science as well as compliance, can achieve a very high success rate both in the outcome of the science and in the acceptance of data for a regulatory submission.

GOOD CLINICAL PRACTICES (GCP)—AN OVERVIEW

Richard A. Guarino

Oxford Pharmaceutical Resources, Inc., Totowa, New Jersey, U.S.A.

BACKGROUND

The Good Clinical Practice (GCP) regulations section in the Code of Federal Regulations (CFR) (21 CFR 312) (1) outlines the respective responsibilities of the clinical investigator, the drug sponsor, and the clinical study monitor involved in investigational new product development. These obligations, along with each participant's moral and ethical responsibilities for the safety of subjects who participate in clinical studies, comprise the essence of GCPs. GCPs have long been the norm for the investigator, as written in the 1572 Form (2); however, the first proposed regulations pertaining to investigator, sponsor, and monitor were first circulated in 1977 and 1978. In 1987, 10 years later, GCPs were published as final regulations in the CFR. Today, investigators, sponsors, and monitors are obligated by law to follow these GCPs.

To conduct clinical research that meets the requirements of the FDA for new product approval, it is essential to understand GCP regulations and their subsequent impact on the clinical development process of drugs, devices, and biologics.

The 1987, Investigational New Drug (IND), regulations specified within the current CFR identify (more clearly than in previously proposed GCP guidelines) the delegation of responsibilities in the conduct of clinical trials. Not only do investigators have a key responsibility in assessing patients' efficacy and safety response to new drugs, devices, or biologics, but the sponsor and monitor also have equal responsibility for the patients' safety and welfare. The key players who are obligated under GCP regulations are described below and will be referenced throughout this article:

Investigator. An investigator is the individual who conducts a clinical investigation (i.e., under whose immediate direction the drug is administered or dispensed to the subject). If an investigation involves many physicians at a particular institution, one physician is designated as the Principal Investigator (PI) and they are the responsible leader of the team of investigators. The subinvestigator is

any other individual member of that team as identified by the PI. These individuals are usually licensed physicians or individuals working under a licensed physician (3).

Sponsor/Investigator. A sponsor/investigator is an individual who both initiates and conducts an investigation (i.e., under whose immediate direction the investigational drug is administered or dispensed). This category refers mostly to physician investigators who are conducting clinical research under an investigator IND (4).

Sponsor. A sponsor is an individual or organization that takes responsibility for and initiates a clinical investigation. This may be an individual, pharmaceutical company, governmental agency, academic institution, or a private or other organization (5).

Monitor. A monitor is the person selected by the sponsor who is qualified by training experience to facilitate and oversee the progress of the investigation (6).

INVESTIGATOR OBLIGATIONS

In 21 CFR 312.53 (7), the regulations deal with the descriptive information provided on form FDA 1572, the Statement of Investigator form. Also included in 21 CFR 312.53 are the selection requirements for clinical investigators. Previously, to conduct studies designated as Phases 1 and 2, investigators were required to complete a Statement of Investigator form FDA 1572; investigators conducting studies designated as phase 3 or phase 4 completed a different Statement of Investigator form, which was known as form FDA 1573. As a result of the IND rewrite regulations, form FDA 1573 is no longer used for any clinical studies. At present, for Phases 1–4, only the Statement of Investigator form FDA 1572 is required. This document states the obligations of investigators conducting clinical research. In addition to the general

information on the 1572, new information includes the following: the name and address of any clinical laboratory facility, the address of the Institutional Review Board (IRB) (8) responsible for the review and approval of the protocol, the patient consent form, and the individual investigators participating in the study. This document also states that the sponsor is charged with the responsibility of selecting qualified investigators, who are defined as those who are capable of conducting the study by virtue of their training and experience. By using the phrase “training and experience,” the FDA means that clinical investigators conducting a study of a particular disease should have enough experience in that clinical specialty to observe correctly the signs, symptoms, and progress of the disease being treated with a new investigational drug. For example, if a new drug is designed for an Obstetrics/Gynecology practice, a pediatrician would not be expected to have the expertise to assess this drug, nor would a cardiologist have expertise in evaluating a gastrointestinal drug.

Investigators are defined as those who have signed and completed form FDA 1572 or sub- or coinvestigators listed on that form, who are considered to have the academic and experiential qualifications for participating in the clinical program.

The “fine print” on the reverse side of form FDA 1572 is a written agreement whereby the investigators assure the sponsor that they will conduct the study in accordance with the appropriate study plan (i.e., the protocol) (9) and will observe the GCP tenets. Implicit in this agreement is the fact that the Investigator will have obtained signed Informed Consent (IC) (10) forms from patients or subjects participating in the clinical research under their jurisdiction. Form 1572 also charges the investigator with the reporting of adverse experiences that occur during the investigation and provides assurance that the investigator has read and understood the investigator’s brochure. In addition, he or she assures that all individuals participating in the supervision of any clinical study, under the direction of the investigator, are aware of their responsibilities. Once form 1572 has been signed by the investigator, he or she further assures compliance with the requirements of providing study materials, protocols, and other pertinent information to an authorized IRB for review. This information, along with a curriculum vitae, should be provided along with the assurance that the investigational plan set forth in the study protocol will be complied with.

To summarize, the primary responsibilities of investigators in clinical trials are the ethical and moral obligations to all the participating patients and subjects in the study. Investigators must provide a measure of safety for each participant in the study so that the patient is

protected ethically and morally from any endangerment that might occur during a trial using an investigational drug. After the investigator’s responsibilities are outlined and he or she has signed form FDA 1572, any additional information from the sponsor that might be necessary should be requested and any concerns regarding procedures should be raised. An investigator is responsible for: 1) ensuring that an investigation is conducted according to the signed investigator statement, the investigational plan, and applicable regulations; and 2) for protecting the rights, safety, and welfare of subjects participating in a clinical investigation on any unapproved product. Also, the investigators must maintain complete control and accountability of the experimental products under investigation. An investigator shall obtain the informed consent of each human subject to whom the drug is administered and shall administer the drug only to subjects under the investigator’s supervision or under the supervision of a subinvestigator responsible to the investigator. The investigator shall not supply the investigational drug to any person not participating in the clinical program.

The investigators are required to maintain adequate records of the disposition of the experimental medications, including dates, quantity, and use by subjects (11). If the investigation is terminated, suspended, discontinued, or completed, the investigator shall account for and return the unused supplies to the sponsor, or otherwise provide written documentation for disposition of the unused supplies of the drug. An investigator is required to maintain accurate case histories designed to record all observations and other pertinent data on each individual treated with the investigational drug. (Usually, this is accomplished by completing case report forms and maintaining medical records).

All investigators shall retain records of all subjects enlisted in investigational trials for 2 years after a new drug application (NDA) is approved for the indication for which the drug is being investigated. If no application is to be filed or if the application is not approved for such indication, records must be maintained 2 years after the investigation is discontinued or the IND is closed and the FDA has notified the sponsor of the status of the application (12).

The investigator shall furnish all reports to the sponsor of the drug. The sponsor is responsible for collecting and evaluating the results obtained. The sponsor also is required to submit annual reports to the FDA on the progress of the clinical investigations.

Investigators shall promptly report to the sponsor any adverse effect that may reasonably be regarded as caused by, or probably caused by, the investigational drug. If the

adverse effect is serious (13) the investigator shall report the adverse effect immediately. (See chapter on ADR reporting.)

An investigator shall provide the sponsor with an adequate report shortly after completion of the investigator's participation in the study.

OTHER INVESTIGATOR RESPONSIBILITIES

The investigator must assure that an IRB complies with the regulations established in the CFR and that the IRB is responsible for the initial and continuing review and approval of the proposed clinical study. The investigator must also assure that he or she will promptly report all changes in the research activity and all unanticipated problems involving risk to human subjects Adverse Reactions (ADRs) or others to the IRB. In addition, the investigator will not make any changes in the research protocol without IRB approval, except where necessary to eliminate apparent immediate hazards to human subjects.

An investigator will on request from any properly authorized officer or employee of the FDA, at reasonable times, permit such officer or employee to have access to, copy, and verify any records or reports made by the investigator. The investigator is not required to divulge subject names, unless the records of particular individuals require a more detailed study of the cases or unless there is reason to believe that the records do not represent actual case studies or do not represent actual results obtained.

SPONSOR OBLIGATIONS

The sponsor's primary responsibility is clearly delineated in 21 CFR 312.50 (14) and ensures that clinical studies are conducted in compliance with FDA regulations. The sponsor is responsible for selecting qualified investigators and for providing them with the information they need to conduct an investigation in accordance with the published regulations. Usually, the sponsor accomplishes this task by supplying the potential investigator with an investigator's brochure and a protocol of the clinical investigation on the agent to be investigated. An investigator's brochure (15) contains all information from nonclinical studies and reports and any previous human efficacy and safety study reports that reflect previous experiences of patients of the investigational agent.

Of primary interest in the obligations is the option of a sponsor to transfer total or partial responsibility for the

conduct of a clinical study to a Contract Research Organization (CRO) (16). During the last decade, CROs have played a significant role in new drug development. However, CROs who contract with sponsor companies are obligated under the same GCP regulations as defined in this chapter. A CRO may be the sponsor or the monitor with equal obligations as defined in 21 CFR 312. The current regulations noted in 21 CFR 312.52 (17) are specific and require that any transfer, whether in total or in part, be described in writing and agreed to by both parties. The FDA states that any obligations not specifically described by the sponsor in the written transfer of responsibilities will be considered as not transferred to the CRO; the liability for these undefined responsibilities, therefore, remains with the sponsor. The FDA further requires the CRO (once any transfer of responsibilities has been made by the sponsor) to comply with all applicable regulations and notes that the CRO is subject to the same regulatory actions as a sponsor if a CRO does not satisfy FDA regulations in the fulfillment of its contracted duties. As a result of these regulations, it is possible for a CRO to act on behalf of a sponsor once this legal transfer of obligations has been completed. Although the CRO must assure complete compliance with the responsibilities assigned, it remains the sponsor's responsibility to ensure the quality and integrity of data generated under the supervision of a CRO. In this situation, the sponsor would be expected to act as a quality assurance (18) auditor of the data, even though assignment for the conduct of a study has been delegated to the CRO. It is important to note the following: that any such transfer shall be described in writing; if not all obligations are transferred, the description of the specific obligations being assumed by the CRO must be clearly stated. Any obligation not covered by the written description shall be deemed not to have been transferred. The regulations also charge the sponsor with responsibility for the inventory and control of the drug. Only investigators participating in a clinical trial may receive and have access to investigational drug and materials.

SPONSOR AND MONITOR OBLIGATIONS

One of the most important responsibilities of the sponsor is to monitor the progress of every clinical investigation conducted under its direction (21 CFR 312.56) (19). A monitor's obligations, under the auspices of the sponsor, are to ensure that the deficiencies created during the conduct of clinical investigations are corrected or justified by the investigator and that the investigator adheres to the

investigational plan. The appointed monitors for any clinical investigation conducted under a sponsor's IND have an obligation to assure that an investigator is complying with the signed Form FDA 1572 and the general investigational plan and that the clinical protocol is being followed. If an investigator does not correct his or her errors and mistakes and no improvement is noted in the progress of the study, the monitor shall promptly secure compliance or discontinue shipment of the investigational new drug to the investigator and end the investigator's participation in the clinical program. In addition the monitors, while monitoring the progress of a clinical investigation, must evaluate the evidence relating to safety and effectiveness. At the same time, sponsors shall make such reports to the FDA regarding information relevant to the safety of the drug, as they are required to do under section 312.32 (20) of the FDA regulations.

When a monitor reports an adverse effect to a sponsor during an investigational study, it is the sponsor's obligation to determine whether there is an unreasonable and significant risk to the subject or patient (21). At that time, the sponsor must determine if the investigational study is to be discontinued. Important among the procedures of reporting adverse effects is the sponsor's obligation to the FDA, the IRB, and to all investigators who, at any time, participate in clinical studies and who are prescribing the experimental drug. Subsequent to this, the sponsor should furnish the FDA with a full report of the sponsor's actions and shall determine whether or not to discontinue the investigation. If the decision to discontinue is made, based on the seriousness of the ADRs reported, the studies should be terminated as soon as possible and no later than 7 days after making the decision.

It is important to understand that the obligations of monitors include the responsibility for assuring that all records and data recorded on case report forms reflect valid data gathered by the investigator and that they coincide with corresponding medical and hospital records of the candidate participating in the investigational study. Detailed auditing and documentation assure the sponsor that the monitor is overseeing the clinical data collected by the investigator and that GCPs are being followed (22). One misconception of many monitors who audit clinical investigations is that their only task is to assure correct entry of data. In fact, it is of extreme importance among the monitor's obligations to note any adverse effects or any deviations in laboratory values that could signify a safety problem to investigational study subjects. This is especially true in large multiclinic studies, in which many centers are conducting investigational studies following the same protocol and many monitors are auditing data. If any abnormal reactions or laboratory deviations are noted

from center to center, the monitors should compare observations and assess an accumulative percentage of occurrence of these deviations. At times, a sporadic, apparently minor deviation can turn out to be a significant deviation when calculated across all centers. If monitors are astute, they can often prevent recurrence of adverse events that might jeopardize the safety of the subjects participating in investigational drug studies.

Another responsibility of the monitor is to assure maintenance of accurate records showing the receipt, shipment, or other disposition of the investigational drug (23). These records are required to include, as appropriate, the name of the investigator to whom the drug is shipped, the date, the quantity, and the batch number of each shipment. The monitor/sponsor shall also assure the return of all unused supplies of the investigational drug from each investigator whose participation in the investigation is discontinued or terminated. The sponsor may authorize an alternative disposition of unused supplies of the investigational drug, provided this alternative disposition does not expose humans to risks. Although the overall responsibilities are assigned to sponsors, it is the monitors' underlying responsibility for drug accountability.

In turn, the investigators, during experimental research, are also responsible for record retention similar to that of the sponsor. They are required to maintain adequate records of the disposition of the drug, including dates, quantity, and use by the subjects or patients. The investigator is also obligated, if he or she is terminated, suspended, or discontinued or if he or she has completed a study, to return all unused supplies of the drug to the sponsor or otherwise provide documentation of how the unused supplies of the drug were disposed. (It is recommended always to return the unused study medication to the sponsor). An investigator is required to prepare and maintain adequate and accurate case histories (designed to record all observations and other data pertinent to the investigation) on each individual treated with the investigational drug. The monitor should assure that all the previous procedures are adhered to and reported in a timely fashion.

An often-neglected investigator responsibility is the requirement to submit periodic reports to the sponsor. An investigator should be prepared to provide the sponsor with progress reports. These should include an update of the ongoing investigational trial. Annual reports to the FDA on the progress of the clinical investigations are required to be submitted by the sponsor. These reports contain information based on the investigators' progress reports (24). Safety reports are another issue. An investigator should promptly report to the sponsor any adverse events that may reasonably be regarded as caused by or likely caused by the investigational drug. Alarming adverse events (i.e., severe

adverse reactions that jeopardize a patient's safety in any way) must be reported immediately by the investigator to the sponsor (25). Lastly, when an investigator has completed or terminated an investigational study, a final report shall be provided to the sponsor. This comprehensive report should be submitted to the sponsor shortly after completion of an investigator's participation in the investigation. The report summarizes the final observations of the study and any adverse events that occurred during the course of the clinical investigation. Monitors should also be responsible for encouraging investigators to complete and submit all the reports listed above. Constant follow-up may be necessary by the monitor if these investigator responsibilities are to be fulfilled. In most cases, the clinical monitor usually will provide the investigator with these reports.

Legal repercussions can occur from any neglect of the obligations by investigators, sponsors, or monitors. The CFR stipulates in 21 CFR 312.58 (26) that the FDA can inspect the sponsor's records or reports on request from any properly authorized officer or employee of the FDA. These inspections normally occur at reasonable times and permit the FDA to have access to copy and verify any records and reports relating to a clinical investigation conducted under an IND. On written request by the FDA, the sponsor may be asked to submit the records, reports, or copies of them to the FDA. Under these regulations, the sponsor is also obligated to discontinue shipments of the drug to any investigator who has failed to maintain or make available records or reports of the investigation. Subsequently, an investigator may, on request from any properly authorized officer or employee of the FDA, at reasonable times, permit such an officer or employee to have access to or copy and verify any records or reports made by the investigator. The investigator is not required to divulge subject or patient names unless the records of particular individuals require a more detailed study of the cases.

GCP NONCOMPLIANCE

What are the consequences if an investigator has repeatedly or deliberately either failed to comply with these GCP requirements or has submitted false information in any report to the sponsor (27)? Initially, the Center for Drug Evaluation and Research (CDER) or the Center for Biologics Evaluation and Research (CBER) will furnish the investigator with written notice of the matter complained of and offer the investigator an opportunity to explain the matter in writing or at the option of the investigator, grant an informal conference. If the

explanation offered by the investigator is not accepted by the CDER or the CBER, the investigator will then be given an opportunity for a regulatory hearing. At this hearing, the issue of whether the investigator is entitled to receive investigational drugs will be addressed. After evaluating all available information, including any explanation presented by the investigator, the FDA commissioner determines whether the investigator has repeatedly or deliberately failed to comply with the GCP requirements or has deliberately or repeatedly submitted false information to the sponsor in any required report. The commissioner will then notify the investigator and the sponsor of any investigation in which the investigator has been named as a participant that the investigator is not entitled to receive investigational drugs. The investigation can not be terminated without reasonable cause as set forth by the commissioner and committee. Sponsor can also suspend shipment of drugs to the investigator for noncompliance to the protocol. If there is reasonable cause for this action, the investigator becomes subject to further investigation for each IND and each approved application submitted to the FDA containing data reported by this investigator. Therefore, every investigational study conducted by this investigator will be examined to determine whether the investigator has submitted unreliable data. Other investigations that are conducted under the same protocol will be temporarily put on hold. Conversely, the commissioner may determine, after eliminating the unreliable data by the investigator, that the remaining data justify continuing other of the same investigations at other sites. However, if a danger to the public health exists, the commissioner will terminate the IND immediately; the sponsor will be notified and will have an opportunity for a regulatory hearing before the FDA on the question of whether the IND should be reinstated. If the commissioner determines that the data submitted are unreliable and that the data submitted by the investigator cannot be justified, the commissioner will proceed to withdraw approval of the drug product in accordance with the provisions of the Food and Drug Cosmetic Act (FD&C). As a result, an investigator who has been deemed to be ineligible to receive investigational drugs will be blacklisted and unable to participate in any experimental studies. The investigator may be reinstated when the commissioner determines that the investigator has presented adequate assurances that the investigator will use investigational drugs in compliance with FDA regulations.

In conclusion, before an investigator accepts the responsibilities to conduct a clinical investigation with an IND drug, he or she must be aware of the legal obligations he or she has agreed to when form FDA 1572 is signed. Investigators must comply with the protocol and the rules, regulations, and guidelines of GCPs.

Investigators must realize that they are subject to a federal offense and can jeopardize their reputation and, ultimately, their ability to conduct further clinical research. Investigators must know that the precise collection of data is mandatory in the conduct of clinical research. Research must be designed to assess the efficacy of the product and, above all, to assure that the safety of the patient remains the primary concern.

Sponsors' and monitors' responsibilities in complying with GCPs are also subject to serious repercussions under 21CFR 312.58. FDA inspectors are allowed to examine sponsors' files and the interventions of monitors' site visits to assure that GCP compliance was executed. Case report forms and clinical results are subjected to the same scrutiny that are applied to the investigators' responsibilities. If during an FDA inspection discrepancies are found in any form among the investigator, sponsor, and, when appropriate, the CRO (i.e., its documents), all three parties will be held responsible, and the IND will be placed on hold until the findings are resolved.

Investigators', sponsors', and monitors' obligations must be fulfilled by complying with GCP rules and regulations. Sponsors' and monitors' consistent and persistent managing roles are vital in assuring that each person involved in conducting clinical studies meet his or her legal obligations. The success of any clinical program will depend on the cooperation, understanding, and compliance of this triad working together. With this agreement of responsibilities and a well-organized clinical plan, the results can only conclude valid data in support of a new drug application.

GLASS AS A PACKAGING MATERIAL FOR PHARMACEUTICALS

Claudia C. Okeke

United States Pharmacopeia, Rockville, Maryland, U.S.A.

INTRODUCTION

Glass has been used for over 6000 years, dating to ancient times. Through the years and with more knowledge of its technology, glass has become the most widely used drug packaging material. The origin of the first synthetic glass is unknown; however, Egyptians were known to mold figurines from sand and silicon dioxide (1). The American Heritage dictionary defines glass as a large class of materials with highly variable mechanical and optical properties that solidify from the molten state without crystallization, that are typically based on silicon dioxide, boric oxide, aluminum oxide, or phosphorous pentoxide, that are generally transparent or translucent, and that are regarded physically as supercooled liquids rather than fine liquids (2).

ASTM defines glass as an inorganic product of fusion that has cooled to a rigid condition without crystallizing (3). ASTM further states that glass is typically hard and brittle and has a conchoidal fracture. Glass may be colorless or colored. It is transparent but may be made opaque or translucent (3). Glass is noncrystalline and is amorphous in structure and may be formed from both organic and inorganic materials.

Glass is manufactured at very high temperatures, and at very hot temperatures, it has the properties of a viscous liquid. With the properties of a viscous liquid, hot glass can be formed into many commonly used forms with precision and accuracy. As a result of its noncrystalline nature, it affords a unique transparent property that is maintained because it does not crystallize upon cooling.

There are a variety of uses of glass, one use being a pharmaceutical packaging material. Glass is favored over other types of packaging material because its transparent property enables it to provide good visualization of contained material. Another good quality of glass is its excellent resistance to attack by most liquids, and, therefore, it resists interaction with contained products. It is also totally impermeable to gases, and it can be sterilized with any appropriate process. Glass, when properly colored, also provides protection of a product from light.

GLASS COMPOSITION

There are two glass compositions generally used—soda-lime and borosilicate. The soda-lime compositions are used for ordinary tableware, food, and beverage products, and window glass, among many others. Borosilicate glass is not widely used, but it is more durable and heat-resistant than soda-lime glass. This glass is used for laboratory and scientific glassware, and heat-resistant cookware, among many others. Borosilicate glass affords properties that make it a preferred composition for certain pharmaceutical containers. Glass composition will be discussed in detail below (4).

GLASS MANUFACTURE AND COMPOSITION

Raw Materials

Silicon dioxide (SiO_2) also known as silica, is the principal constituent of glass. Glass is made by melting its ingredients at very high temperatures, such as 1550°C . Because the melting point of silica alone is so high, and, therefore, commercially difficult to melt and form into containers, other oxides are added to silica to lower the melting point and make it easier to fabricate and use commercially (5). These oxides include sodium oxide (Na_2O); aluminum oxide (Al_2O_3); potassium oxide (K_2O); boron oxide (B_2O_3); and calcium oxide (CaO). The addition of one or more of these oxides reduces the melt viscosity for fabrication purposes. Other materials may be added to change a color, facilitate melting, or for other reasons. Sodium and potassium oxides are obtained as the product of chemical processing of naturally occurring materials, and an abundant source is the brines of Searles Lake in California. Sodium is primarily added to silica to lower the melting temperature and aid in the removal of gas bubbles in a reasonable time. Potassium oxide is used in smaller amounts. All of these additives change the properties of silica in such a way that the resulting glass is less resistant to attack by aqueous solutions. Other additives such as calcium oxide, magnesium oxide, and aluminum oxide are also used in various amounts to affect

the properties of the glass. Silica has a very low coefficient of thermal expansion, and the addition of an alkali such as sodium oxide increases the thermal expansion.

When fluxing action is needed during melting and glass with high thermal expansion is undesirable, boric oxide is added forming borosilicate glasses, which have lower thermal expansion and improved resistance to attack by aqueous solutions because of lower sodium oxide contents.

Conditions necessary for glass formation may be deduced from either geometric or bond strength considerations. Silica sand deposit is available in all parts of the world. Silica sand is mined by hydraulic dredging, and any impurities are eliminated through further processing. One impurity, iron oxide, may be present, and, if present, may affect the final color of the glass (4). There are other oxides that are potential glass formers and may be used in glass formation: GeO_2 , P_2O_5 , As_2O_5 , P_2O_3 , As_2O_3 , Sb_2O_3 , V_2O_5 , Sb_2O_5 , Nb_2O_5 , and Ta_2O_5 (6). Pharmaceutical containers may require amber glass to provide protection for light-sensitive pharmaceutical products. Amber glass is available in both soda-lime and borosilicate. The amber glasses have negligible transmission in ultraviolet (UV) and near UV regions and, hence, provide the required protection. In these cases, glass is interacted with iron oxide to provide amber color.

For pharmaceutical products that undergo sterilization by means of ionizing radiation, cerium oxide of about 1% or less is added to the glass formulation. This is because ionizing radiation type sterilization [dosages as high as 20–30 kGy (2 to 3 Mrad)] affects ordinary glass by darkening the glass and, thus, inhibits the final inspection of the glass products.

The mechanism by which ionization radiation acts on glass is by dislodging the electrons in the glass structure (usually intermediate density and low cost glasses) to form color centers and creating changes to the multivalent ions in such a way that they absorb visible. The result is a formation of neutral atoms such as sodium that can agglomerate into colloid-like configurations. Cerium oxide, which is multivalent when added to the formulation, counteracts the darkening effect of radiation by capturing these free electrons and minimizing the deleterious effects without adding color to the glass (4).

All raw materials used to formulate a glass composition should be characterized using certain specifications of particle size, distribution, overall purity, and specific impurity content. It is necessary to match the particle size of the raw materials as much as possible to allow trouble-free melting.

Also classified as a raw material is cullet. Cullet is a scrap glass of desired composition, which results from scrap generated during forming operations and kept

strictly segregated by composition. Cullet is then recycled through the melting process. The use of cullet conserves raw materials and aids in the melting process. A typical diagram illustrating the process in glass manufacturing is shown in Fig. 1 (1).

FORMULATION—BATCH MIXING, CHARGING, AND MELTING

In a typical factory, a batch formulation is developed that provides the desired glass composition when melted. The raw materials are stored in large capacity silos. Depending on the type of plant facility, the raw material may be proportioned and mixed by a computer programmed with the batch formulation. The computer functions to control the automatic material transport system, weighing equipment, withdrawing the correct amount the raw materials from the perspective silos, and discharging them into a large mixing vessel. After mixing for the desired time, the batch is discharged into cans of mixed batch. These cans are transported to the charging end of the melting furnace. Complete records are maintained for the weighing, mixing, and transportation of batch materials to the furnace.

Usually, when the intimately mixed batch is charged into the hot furnace, a series of melting, dissolution, volatilization, and redox reactions occur between the materials in a certain order and at the appropriate temperature (7). At the furnace, the batch contents are discharged through a screw feeder into the furnace, with temperatures capable of exceeding 1700°C. The batch floats on the surface of the glass already in the furnace and gradually melts into the desired glass composition. The temperature of the furnace is necessary to facilitate melting and producing glass of the desired homogeneity in a commercially acceptable time. The glass is allowed to stay in the furnace until a satisfactory homogeneous product is formed, after which the temperature is lowered at the discharge end to achieve a glass viscosity that allows the desired forming operations to take place.

In most cases, the glass made cannot be characterized by a batch or lot designation but only by the date and time of withdrawal from the furnace. This is because the glass-melting process is a continuous process, even though the glass materials are charged in discrete amounts. The residence time in the furnace permits extensive mixing to occur and, therefore, erases all identity of the batch from individual cans (4).

Devitrification is the uncontrolled formation of crystals in glass during melting, forming, or secondary processing. The optical properties, mechanical strength, and some-

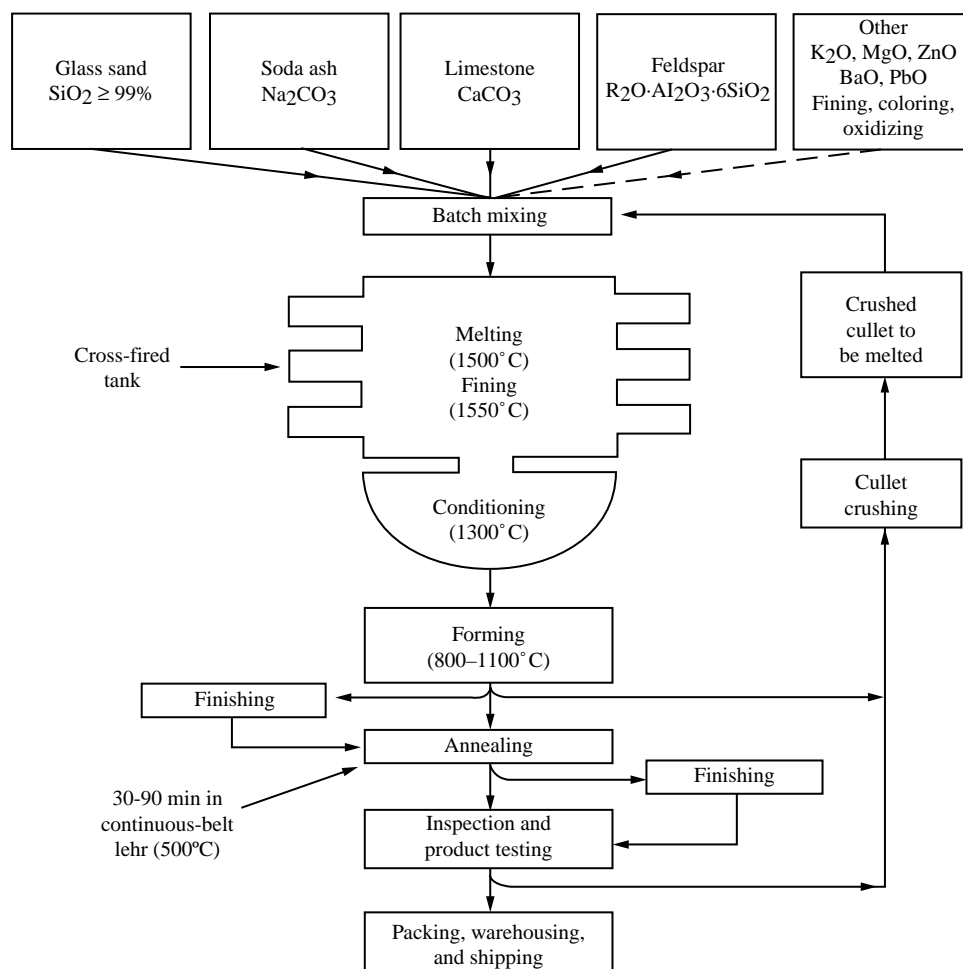

Fig. 1 Glass manufacture. Temperatures used may vary depending on the type of glass. (From Ref. 1).

times the chemical durability of the glass can be adversely affected by devitrification. These unwanted crystals grow homogeneously within the glass or heterogeneously at the air-glass or refracting-glass interface. Devitrification occurs mainly in glasses where the optimum temperatures for maximum nucleation rate and for maximum growth rate nearly coincide. If these glasses are held too long in this critical temperature range or are cooled too slowly through it, the glass starts to crystallize. For soda-lime glasses, the crystal phase, devitrite, forms between 850–900°C. However, since the glass is already quite viscous, the critical temperature range is short, and devitrification is not much of a problem (1–3).

QUALITY OF A GLASS PRODUCT

Following a successful product fabrication, there are some qualities to observe, one of which is total homogeneity of

product. Most glass manufacturers try to ensure that composition of the glass is homogeneous throughout. However, gas bubbles that did not escape the body of glass while in the furnace may cause a nonhomogeneous composition to exist.

Glass bubbles in manufacturing result from chemical reactions that take place during melting. Glass bubbles evolve due to the following: 1) because of gas formation from decomposition of the carbonates or sulfates or both; 2) from air trapped between the grains of the fine-grained batch materials; 3) from water evolved from the hydrated batch materials; and 4) from the change in oxidation state of some of the batch materials, such as red lead. However, with enough time in the furnace, the air bubbles escape the melt by rising slowly to the top. In some cases, the gas bubbles may be withdrawn with glass from the furnace. These bubbles are called seeds or blisters. They are not desirable and may be a cause for rejection of the final glass product, depending on the size and extent. When the

surface of a glass final product is broken by the bubble, it is considered a functional defect. However, if the bubble is surrounded by glass, it is considered a cosmetic defect, and while generally it may not be hazardous, it may still be rejected.

Cord is another attribute in glass formation that is not desirable and should be prevented. Cords are formed when glass is not stirred properly at appropriate places in the furnace. It is referred to as the act of improper homogenization. Typically, in this case, glass melting occurs at a very high temperature, and some constituents vaporize from the surface glass and form regions of viscous glass. When small amounts of this glass mix into the body of the melt, they appear as very narrow and long inhomogeneous regions, referred to as cord (4).

Batch segregation, melt segregation, volatilization, and temperature fluctuations, as well as refractory corrosion from tank-lining material, cause stria or cord formation as well. These can also be prevented by melt homogenization and vigorous fining action. The homogeneity leading to cord formation can be removed by diffusion and flow and by vigorous fining, along with convection current mixing process before the glass is cooled. Homogeneity can also be improved by mechanical and static mixers that continuously shear the glass.

The bubble and cord defects that occur during the melting process are the two most commonly encountered. Melting defects should be held to a minimum as much as possible.

Fining is the physical and chemical process of removing glass bubbles (seeds and blisters) from the molten glass melt. Typically, fining agents that react at higher temperatures than are needed for melting are used. Some examples of fining agents are sulfates and sodium-potassium nitrates in combination with arsenic or antimony trioxides. Arsenic trioxide is used for melting glasses at higher temperatures, e.g., 1450–1500°C, whereas antimony is used for lower melting glasses at 1300–1400°C. As glasses cool, oxygen bubbles are removed by the reaction with arsenic or antimony trioxide to form pentoxide (1).

Gas may be evolved from a typical amber soda-lime glass batch, and fining agents are usually employed to resolve the problem (8). A typical batch mixture for amber soda-lime container glass is shown in Table 1.

QUALITY CONTROL IN BATCHING AND MELTING

Producing glass containers for parenteral products requires strict control of all process aspects, starting with raw

materials and ending with the testing of glass as a material and as containers or parts of medical devices. The objectives of a quality-control program should be to maintain glass produced within physical and chemical specifications and to prevent off-specification material from reaching the pharmaceutical manufacturer.

Normal practice is to make sure that the raw material meets desired specifications and maintains its integrity during loading and shipping. There are physical as well as chemical requirements associated with each raw material, and these requirements are met by controlling for desired behavior during batching and melting and by the desired properties of the final glass product. The chemical impurity content is usually dictated by the desired attributes of the glass container. For example, raw materials of low iron content are used in order to provide a virtually colorless final product. Raw materials of low sulfur content (in the case of borosilicates) are used to minimize gas bubble formation during melting. Substances that would be harmful if extracted from the glass during terminal sterilization and subsequent storage (e.g., lead or arsenic) should be absent (4).

Most raw material suppliers provide certificates of analysis for the material they provide, and the information is checked by further testing on receipt. Records of performance of raw materials are maintained. The vendor's production facilities are usually inspected to ensure that mixing of raw materials of different grades cannot occur during loading and shipping. Ideally, this is a desirable situation and should be the goal of quality-oriented raw material suppliers and the glass manufacturers.

Scrap glass, or cullet, is also considered a raw material. Proper handling of cullet to prevent mixing of compositions and contamination by foreign materials requires constant attention and is just as important as preventing contamination of a raw material received from outside the plant.

Special considerations should be applied to ensure that all glass batch formulations are prepared by qualified technologists. The formulation for each composition is given in a batch sheet, which specifies the glass type, melting tank, date issued, amounts of raw materials, total batch weight, and weight of glass expected from the batch. In some companies, batch sheets are under the strict control of the glass-technology department, and each sheet denoting a change requires approval by several levels of department management. Changes are made primarily to manage the cullet supply, which can vary. Batch sheets usually provide a continuous time record of a given composition melted in a given furnace, and the batch sheets are supplied to the department responsible for actual

Table 1 Typical batch mixture for amber soda-lime container glass

Batch materials	Oxides supplied (kg)						LOI ^a (kg)
	Weight (kg)	SiO ₂	Al ₂ O ₃	CaO	Na ₂ O	FeO

^aLoss on ignition. Generally, the oxides of carbon and sulfur (plus some chlorine, depending on the fining agent) volatilize during melting.

^bAlso 0.2 kg MgO or 0.02 wt%.

^cAlso 4.1kg K₂O or 0.45 wt%.

^dUsed primarily to reduce the Fe₂O₃ to FeO to give the characteristic amber color, although the redox state of the glass melt also influences the fining reactions.

(From Ref. 8.)

weighing and mixing of the raw materials. In most companies, batching and mixing operations are usually under computer control, involving automated weighing, mixing, and conveying operations. Great care is to be exercised in entering the batch formulations into the computer, with continual checking for accuracy.

The next step is the testing of the glass produced. The testing program may be based on the following: 1) glasses are melted in large furnaces in a continuous operation, and the chemical and physical properties of any glass are dependent on one another; 2) continuous melting in large furnaces does not create abrupt compositional changes as might be experienced with discrete batch melting; 3) changes take place slowly in the furnace because of the size and volume of glass contained; therefore, periodic sampling and testing is a necessary production control. Measurement of selected physical properties serves to determine the values of all other relevant physical properties and also serves to define the chemical composition (4).

Samples of glass can be obtained daily from every producing position and subjected to a variety of tests. Each test is performed sufficiently often to ensure product quality. The following properties are determined:

- Seal stress
- Softening (viscosity) point
- Annealing and strain points
- Density
- Light transmission

- Chemical durability
- Chemical analysis

For most manufacturers, seal stress is determined on a daily basis and is a primary indicator of any shift in glass composition. Typically, a sample of daily production is flame-sealed or fused to a reference glass of the same composition having the desired target properties. Any deviation in composition is reflected in the generation of stress in the seal area. The physical property inferred from this test is thermal expansion, which is highly sensitive to changes in alkali content that, in turn, influence the chemical durability. If the test results show sufficient deviation from internal specifications, corrective action is initiated by issuing a slightly modified batch sheet. The effects of the corrective action should be observed in the next day's production.

The other tests mentioned may be performed in time intervals ranging from weekly to biweekly and monthly. The results of all these tests provide a framework describing glass quality on an ongoing basis. Thus, if the daily seal stress and the weekly viscosity points and biweekly chemical durability tests are satisfactory, the monthly chemical analysis will be right on target. It also follows that glass produced at any time, although not specifically tested for durability, will, in fact, be satisfactory if the other tests are satisfactory. In addition, an interlocking database can be used to certify to the pharmaceutical manufacturer that glass produced at any time meets specified requirements.

Process of Forming Pharmaceutical Containers

Pharmaceutical containers can be made by a blow-molding process and by a glass rod or tube-shaping process. Commonly, the large-volume parenterals of 100 ml or more are made by a blow-molding process, whereas small-volume parenterals of 100 ml or less are made by the tube-shaping process.

Although for the purpose of this section, discussion will be limited to pharmaceutical containers, molten glass can be formed in all kinds of shapes and sizes, such as bottles, jars, etc. Molten glass is either molded, drawn, rolled, or quenched, depending on the desired shape and use.

Blow-Molding Process

The blow-molding process uses hot glass as it leaves the furnace. The glass must be at the correct temperature and viscosity for forming to be successful. This process describes a typical blow-molding process. At the exit end of the furnace, the glass flows through an orifice in the bottom of the furnace section called the feeder. A pair of cooled blades cuts the glass stream into discrete chunks called gobs. The gobs contain the correct volume of glass to make one container. The gob is delivered into blank molds where it is settled with compressed air and, ultimately, forced to conform to the interior shape of a cast-iron mold that represents the bottle. This preformed (cast-iron mold shape) stage is obtained with a counter-blow of compressed air. The formed bottle is inverted and transferred into the blow mold where it is further finished by blowing. The mold is hinged so that it opens and allows the removal of the bottle. The bottle is sent through a controlled cooling process, known as annealing, which allows the bottle to cool down to room temperature in a stress-free condition. A press-and-blow machine, such as the Hartford-Empire machine, is an example of a blow machine used for making articles such as drinking glasses. A typical process of blow-and-blow machine is shown in Fig. 2.

Blow-molded containers can be made in clear glass or glass that has been colored for protection of the product from light. In comparison to the tubing process which will be discussed later, the walls of blown containers are usually thicker than those of the tubing process, and, hence, blow-process containers have greater impact strength. However, containers made from tubing process have more uniform distribution of glass in the walls. This may be critical, depending on its intended use, and may impact on optical-inspection equipment. Blow process containers also have thicker bottoms, and this could affect heat transfer during lyophilization.

Tubing Process

The Danner process is a common method used for glass tubing, which is a mechanical process. There is also the hand drawn process described below. Glass tubing can be made with a precisely controlled outside diameter (OD) and wall thickness. There is an upper size limit of about 40-mm OD, which is not a limitation on the tubing-forming process, but on the subsequent forming operations used to make containers. In the hand drawn process, about 15 m of 140-mm OD, 2-mm wall thickness tubing can be made on one draw by a gaffer and two helpers. Gathers of glass up to 30–35 kg can be made with bubble in their center at the end of the blow pipe. This is rotated in place by the gaffer, and rotated and stretched out by one of the helpers walking away from it. The size and the diameter of the tubing is a function of the helper's walking speed and is further controlled by a second helper that cools the tubing by fanning at specified times. Up to 150 m of the much smaller diameter thermometer tubing can be made in this manner from one gather (1, 4, 9).

In the Danner process, a continuous stream of glass, of the proper temperature, flows slowly and controllably onto a rotating mandrel, which is an inclined cylinder made of refractory ceramic materials or of platinum alloy. Glass tubing is drawn off the end of the mandrel, which is tapered, while air blowing through the mandrel helps to maintain tubing dimensions. This air is pressurized to keep the tubing from collapsing toward the end. The glass temperature controls the diameter and the wall thickness of the tubing, the inflating air pressure, and the rate of withdrawal of glass from the cylinder. A schematic representation of the Danner process is shown in Fig. 3.

When tubing has cooled sufficiently, it is cut into lengths convenient to handle and is used as feed stock for the container-forming process. Hairpin cords of inhomogeneity and volatilization from the surface are capable of occurring during the tubing process. The tubing process can be used to make ampuls, vials, syringe barrels, cartridges, and a variety of containers used in medication delivery (4).

Another type of tubing process is the Vello process. In the Vello process, the molten glass passes down through an annulus between a horizontal ring and a vertical bell. The moving stream connects to a nearly horizontal runway, and as in the Danner process, it is drawn off at a suitable rate for dimensional specification and stability. The Vello process forms tubing faster because the glass is cooled more quickly to the appropriate forming viscosity in a stationary forehearth of the desired dimension. However, the Vello

Fig. 2 The H.E. IS blow-and-blow machine (9). The gob is delivered into a blank mold, settled with compressed air, and then preformed with a counter-blow. The parison or preform is then inverted and transferred into the blow mold where it is finished by blowing. (From Ref. 9.)

process is more difficult to operate and is most suitable for longer production runs having few size changes (1).

In comparison to sized molded containers from the blow-molded process, tubing process containers are made lighter in weight and provide more precisely controlled

dimensions than blow-molded containers. The walls and bottom thickness are more uniform, and, hence, are more suited for use in automatic inspection Systems. Clear and light resistant glass compositions can be used in the tubing process.

Fig. 3 The Danner process for manufacture of tubing.

GLASS COMPOSITION, PROPERTIES, AND CLASSIFICATION

As mentioned earlier, the focus in this article is on soda-lime-silica glasses and borosilicate glasses.

Soda-Lime-Silica Glasses

These compositions are for glass for every day use. The batch materials for soda-lime glasses are easily available at reasonably moderate cost. These materials readily meet at moderate temperatures. These glasses have a relatively high thermal expansion coefficient and only moderate resistance to attack by a contained product.

The actual compositions of soda-lime are usually more complex than the term soda-lime suggests. As mentioned earlier, these glasses may contain MgO , Al_2O_3 , BaO , or K_2O and various colorants, in addition to Na_2O , CaO , and SiO_2 . Alumina increases the durability of soda-lime glasses, whereas MgO prevents devitrification. Soda-lime glasses account for 90% of all glass produced and are used

for containers, flat glass, pressed and blown ware, and some types of lighting products (1).

In soda-lime glasses, the amber color is developed by the interaction of iron oxide and a small amount of sulfur (a few tenths of a percent), in the presence of a reducing agent during melting. As such, soda-lime amber glasses are called reduced ambers. Typical compositions of soda-lime and borosilicate glasses are presented in Table 2 (4).

Borosilicate Glasses

Borosilicate glasses are developed to meet more stringent requirements than soda-lime glasses. Because of their composition, these glasses require higher melting temperatures and more costly batch materials. As a result, these glasses are more expensive than soda-lime glasses.

Borosilicate glasses are also known as heat-resistant glasses because they have a lower coefficient of thermal expansion than soda-lime glasses and, hence, are more resistant to fracture from rapid temperature changes

(thermal-shock resistance). Borosilicate glasses are used widely as laboratory apparatus, chemical process piping and drain lines, and for baking and cooking dishes in the home. Borosilicates have excellent resistance to chemical attack, and this augments their use as laboratory apparatus and in packaging of pharmaceuticals as containers. The fluxing action of the boron facilitates melting by weakening the network. This is due to the presence of planar three coordinate boron, which weakens the silicate network at high temperature. Borosilicates are divided into two groups based on the coefficient of thermal expansion.

In borosilicate glasses, the amber color is developed through interaction between iron oxide and titanium oxide or iron oxide and manganese oxide. Reducing agents are not used in borosilicate glasses for color development. Borosilicate ambers are called oxidized ambers.

PROPERTIES OF GLASS

Rheology, the melting, forming, annealing procedures, and limitations of use at high temperature, is determined by the viscosity of the glass. Viscosity is measured between 10(13) and 10 Pa.5 [10(14) and 100 P]. Also, viscosity of glasses is compared qualitatively. The addition of modifiers to a glass can alter the viscosity at certain temperatures. At low temperature, the effects of a modifier on viscosity are controlled by its coordination number. Modifiers with high coordination numbers tend to

increase low temperature viscosity due to packing restraints (1).

ASTM provides definition for the procedures and selected reference points discussed in this chapter. Some frequently used reference points are annealing points and strain points. Below are presented some of the ASTM (3):

- *Annealing*: a controlled cooling process for glass designed to reduce residual stress to a commercially acceptable level and to modify structure.
- *Annealing Point (A.P.)*: that temperature corresponding either to a specific rate of elongation of a glass fiber when measured by Test Method C336 or a specific rate of midpoint deflection of a glass beam when measured by Test Method C598. At the annealing point of glass, internal stresses are substantially relieved in a matter of minutes.
- *Annealing Range*: the range of glass temperature in which stress in glass can be relieved at a commercially practical rate. For purposes of comparing glasses, the annealing range is assumed to correspond with the temperature between the A.P. and the strain point (St.P.).
- *Strain Point (St.P.)*: that temperature corresponding to a specific rate of elongation of a glass fiber when measured by Test Method C336 or a specific rate of midpoint deflection of a glass beam when measured by Test Method C598.
- *Softening Point (S.P.)*: that temperature at which a glass fiber of uniform diameter elongates at a specific rate under its own weight when measured by Test Method C338. The viscosity at the softening point depends on

Table 2 Typical compositions and thermal expansions of soda-lime and borosilicate pharmaceutical glasses

Weight %	Soda-Lime			Borosilicate				
	Blow molded		Tubing	Blow molded		Tubing		
	Clear	Amber	Clear	Clear	Amber	Clear	Clear	Amber
SiO ₂	73.0	71.9	67.7	67.8	66.7	80.4	72.0	69.2

(From Ref. 4.)

the density and surface tension. For example, for a glass of density 2.5 g/cm^3 and surface tension 300 dynes/cm , the softening point temperature corresponds to a viscosity of $10^{6.6} \text{ Pa}\cdot\text{s}$.

Discussion

At the strain point, internal stresses are substantially relieved in a matter of hours (3).

The Margules Viscometer, a calibrated instrument that measures the force exerted by molten glass on a rotating spindle can be used to measure viscosity. Glass is usually melted and fined at viscosities between 5 and 50 Pa·s (50–500 P). However, the forming and final viscosity requirements may differ. Hard glasses usually have a high softening point whereas soft glasses have a lower softening point. The length of a glass (i.e., long or short) can be used to explain the differences between the strain point and the softening point of glass. A long glass usually has a large difference between the strain point and the softening point, meaning that it solidifies slower than a short glass as the temperature decreases (1).

The temperature required for glass to form into useable shapes is usually above 1000°C for borosilicates and less than 1000°C for soda-lime. The annealing process is very effective in relieving the residual stresses contained in formed glass (10). The temperature range for proper stress-relief annealing of borosilicate is $600\text{--}650^\circ\text{C}$ and less for soda-lime. These forming stresses are relieved within minutes at these temperatures, and a subsequent slow cooling to room temperature retains the stress-free state.

Thermal Expansion

The value of thermal expansion is important in determining how a glass container survives sudden changes in temperature, that is, thermal shock resistance. The thermal expansion of a glass determines the range of materials to which it can safely be sealed. The thermal expansion characteristic indicates how much change in dimension (e.g., length) the article undergoes upon a change in temperature. The change in dimension in turn determines the stress generated in the glass. The ability of a glass as a heat exchanger thermal barrier and its ease of melting and forming depend on its heat-transfer properties and emissivity. In most cases, glass expands when heated and contracts when cooled. If the thermal cycle is slow enough, there is no hysteresis effect. The slope of linear expansion vs. temperature is known as the thermal expansion coefficient, α , which is virtually constant between 0 and 300°C for most glasses. However, as the temperature of the glass rises to near the set point (strain

point $+5^\circ\text{C}$), the thermal expansion increases more rapidly. Glasses used to the extreme limits are vulnerable to thermal shock, and tests should be made before adapting the final design for any use.

For soda-lime glasses, when expansion is high, the stress is high, and the probability of fracture is greatly increased. Borosilicate glasses have lower coefficients of expansion than soda-lime compositions and, hence, can withstand larger temperature changes without fracture. This is important in processes where relatively rapid temperature changes occurs such as in dry-heat sterilization and lyophilization, among other processes.

Stresses caused by steady-state thermal gradients may or may not cause failure, depending on the degree of constraint imposed by some parts of the item upon others or by external mounting. Thermal stress resistance (face-to-face temperature differentials) that causes tensile stress is observed in some types of glasses. When glass is suddenly cooled, as by the removal from a hot oven, tensile stresses are introduced in the surfaces and compensating compressional stresses in the interior. On the other hand, sudden heating leads to surface compression and internal tension. In both cases, stresses are temporary and disappear once temperature uniformity is reached. Also, because glass fractures only in tension, usually at the surface, the temporary stresses from sudden cooling are much more damaging than those from sudden heating, assuming all surfaces are heated and cooled at the same time. Thermal shock endurance is generally determined by empirical testing because the strength of glass is greater under momentary stress than under prolonged load. Resistance to breakage can be determined by heating the ware to some appropriate temperature then plunging it into cold water. For example, a resistance of 150°C means that no breakage occurred on heating to 150°C and plunging the glass into water at 15°C . A much higher value of thermal shock can be recorded when other cooling media such as air or oil are used (1).

The thermal shock that a container receives as its temperature is lowered depends on the temperature differential and the time required to reach the lowest temperature. Glass as a material can withstand very low temperatures, but sufficient time must be allowed to reach the low temperature in order to avoid breakage. Although it might seem that thick glass walls withstand thermal shock better because of higher strength, the fact is that thin walls resist thermal shock better because temperature change is accommodated more rapidly, lessening the stress created by the temperature differential (4).

The thermal expansion coefficient depends on the glass composition. It is usually assumed that the lower the expansion the better, but this is not necessarily true. It is

true, if soda-lime glass with an expansion of about 90 is compared to borosilicates with expansion coefficients of 33–55. However, there is little to choose from between borosilicates in this range of expansion values. Glasses with expansion coefficients in this range perform satisfactorily under most circumstances. If the application requires cooling rates higher than normally experienced, the lowest expansion glass is of course the choice.

GLASS CONTAINER CHARACTERISTICS: COMPARISON OF BLOW-MOLDING AND TUBING PROCESS

As described earlier, some containers are made from tubing and some by the blow-molding process. Containers made from tubing have a maximum capacity of about 50 ml and a 40-mm OD. Blow molding is more suitable for larger sizes and is used for containers greater than 100 ml in volume. This flexibility in size causes great variation in wall and bottom thickness and weight (4).

Tubing used for containers is produced with closely held dimensions, including wall thickness, wall uniformity, cross section, and straightness. Because these dimensional attributes are strictly controlled, smaller volume containers can be made to much better dimensional precision and accuracy. At the same time, containers made from tubing are likely to exhibit different glass defects than blow-molded containers, mainly because of the kind of defects associated with the manufacture of tubing. Gas bubble inclusions, for example in blow-molded bottles, have a spherical or ovoidal shape, whereas those made from tubing have “air line” gas bubbles that have been stretched out during the forming of the tubing.

Another distinction between the two types of containers is the interior surface composition. For glass to be readily formed, it must be heated to a sufficiently high temperature. Because of this, the more volatile glass constituents tend to escape the surface and condense in cooler regions. This effect is minimal in blow molding, because every part of the forming process leads to lower temperatures, reducing the tendency to vaporize. Containers from tubing, on the other hand, are formed by reheating tubing in specific regions of a tubing length. The result is that some parts of a vial, for example, experience very high temperatures, whereas other parts are barely above room temperature. A typical example of this is the forming of the vial bottom. The glass temperatures required cause vaporization of sodium and boron oxides, together with some chlorides; these compounds condense on the interior vial sidewall, just above the bottom. These so-called

forming deposits or “bloom” can be removed by reevaporation during the annealing step, or if this process is incomplete, by washing later.

A special discussion of tubing containers for lyophilization is warranted because a proper design embodies a combination of container and product characteristics that should be taken into account. Blow-molded bottles for lyophilization, although subject to some manufacturing control, cannot be made as uniquely as tubing containers. The same design considerations apply but are under much less control.

The following considerations have been found to be important in the design and use of containers for lyophilization:

- Product characteristics
- Amount of fill
- Thermal shock
- Glass composition
- Container wall thickness
- Container contours
- Container surface damage

The great variability in products to be lyophilized implies that there will be behavior variations in these products as they freeze. Any glass container considered for use should be evaluated with the actual product, rather than trying to simulate product behavior with test solutions.

The result of product freezing and thawing is internal pressure generation. If the container is overfilled, excessive pressure can result with subsequent container breakage. Fills of less than 50% of the container volume are recommended, with an optimum of about 35%.

The contour of the container is important in resisting the forces encountered during product freezing and in ensuring adequate heat transfer through the bottom. There should be as gradual a transition as practicable between the sidewall and the bottom, to reduce the stress concentration effect caused by this angle. A sharp, re-entrant angle between the sidewall and bottom is the worst condition. In addition, a flat bottom with a little “push up” in the center is best for heat transfer. This condition is in concert with a gradual transition in the heel region; both conditions improve performance.

Everything mentioned above as factors for satisfactory performance can be negatively affected by damage to the surface of the container. The container must be as free as possible of scratches, scuffs, impact damage, etc., if the design criteria are to be effective. Maintaining a damage-free glass surface is also a requirement of the filling line, where contact with sharp metal objects should be minimized. The factors discussed above demonstrate that other factors are of importance beside low glass thermal

expansion, usually the first and sometimes the only criterion considered (4).

Chemical Property—Durability

ASTM defines chemical durability as:

the lasting quality (both physical and chemical) of a glass surface. It is frequently evaluated, after prolonged weathering or storing, in terms of chemical and physical changes in the glass surface, or in terms of changes in the contents of a vessel (3).

One of the main reasons for using glass compared to other containers or packaging material is due to its resistance to chemical corrosion. The chemical durability of a glass varies from highly soluble to highly durable, depending on its composition and the solvent used. Glass used in packaging parenteral products and in direct contact with parenteral liquids or solids must have good chemical durability. Analysis are usually based on measurements of weight loss, changes in surface quality of the glass or finished container, or analysis of solutions that were in contact with a glass. A method of determining the durability of a glass is by subjecting grains of uniform size distribution to accelerated attack by high purity water at a temperature characteristic of terminal steam sterilization. In addition, glass compositions can be directly compared with respect to their resistance to attack by aqueous solutions because glass grain are prepared and sized uniformly. These processes will establish the intrinsic durability of the glass. However, the presence of other factors, such as glass constituents that may condense on the surface during high temperature forming process or other volatile deposits, can reduce or improve the durability.

When glass is attacked by water under accelerated test conditions, the pH of the solution increases as a result of an ion exchange process between the alkali (primarily sodium) content of the glass and the hydrogen ions in solution. The higher the pH, the less durable the glass. At large increases in pH, there are high effects on the contained parenteral product and there is an accelerated attack on glass. The extent of pH change can then be determined by titration of attacking solution with diluted acid. Glasses are rated based on the volume of diluted acid required to neutralize the extracted alkali. Additionally, the extent of attack can be determined by the analysis of the solution for specific constituents, including sodium, boron, aluminum, calcium, and silicon. The amount of acid required to neutralize the extract solution will correlate with the amount of specific glass constituents found in the solution by direct analysis. The most durable glass will require smaller volumes of acid and lower concentration of the constituents in solution.

These observations apply generally to both glass grain tests and container tests, except that the acid volumes and constituent concentration are much lower when testing containers because of a much lower glass surface-to-solution volume ratio.

The reaction of acids with glass may be either a leaching process or a complete dissolution process. Acids such as hydrofluoric acid attack silica glasses by dissolving the silica network. Other acids such as hydrochloric acid or nitric acid may react by dissolving certain glasses. However, the reaction mechanism is by selective extraction of alkali and the substitution of protons in a diffusion controlled process.

The reaction of bases with most silicate glasses produces dissolution rates when tested in 5% NaOH solution at 95°C. The mechanism also involves a complete dissolution process as that described for acid. Weaker alkaline solutions may both leach and dissolve and sometimes show greater dependence on glass composition. And, in the case of strong alkali solutions, the rate of attack doubles for each 10 K increase in temperature or each increase in pH unit. Usually higher alkali durability glasses are used for laboratory wares.

Also, as stated earlier, the attack of water, is related to the leaching mechanism described for acid. Low alkali, high alumina, or borosilicate glasses generally have high water durability. Weathering of glass is the result of the action of water, carbon dioxide, and other constituents. Water initially is absorbed by the glass and then exchanged for alkalies that form alkali salt solutions and, if left in contact with glass, may cause additional damage. As a result, weathering resistance may not correlate with acid durability. Test methods to accelerate the weathering process are designed in chambers at 50°C and 98% rh.

A comparison of the chemical durability of soda-lime glasses and borosilicate glasses show that borosilicates are far more durable than soda-limes, requiring from 10 to 20X less acid to neutralize solutions in glass-grain tests. This is due to the significantly lower alkali content of the borosilicates. The same result applies when comparing containers made from borosilicates and soda-lime. Thus, when product-container interactions must be limited, as in the case of parenterals, the compositions of choice are the borosilicates.

SPECIAL TREATMENTS

Special treatments include treatments to the container after it has been formed into its final shape. These processes can be performed before or after the annealing process. The

processes discussed here are concerned with printing and “sulfur” treatment to improve the chemical durability of the interior container surface.

Printing Treatment (4)

The printing of pharmaceutical containers may involve either applying the printed information as a step in the manufacture of the container or applying of labels as the filled container is processed by the pharmaceutical manufacturer. The printing of information on the container while still in the hands of the glass manufacturer is significant. A number of issues are connected with this, one of which is the strict accountability by the glass producer for containers printed with information on drug type, lot number, etc. Stringent safeguards must be employed during printing to ensure the integrity of the container lots.

Material for printing on glass can include ceramic glazes, epoxy formulations cured by heat, and ultraviolet curing formulations. The latter two are applied after annealing, as the temperatures applied would destroy these materials. Ceramic glazes are applied before the annealing step and have properties such that the annealing temperatures are sufficient to fire on the glaze.

Ceramic glazes provide the most durable type of printing. They are vitreous or glass-like in nature, and form a strong bond with the glass substrate. Ceramic glazes are chemically the most durable. They provide the greatest resistance to abrasion and the highest hardness. However, the glaze and the glass have to be carefully matched. A great disparity in the thermal expansions of the two materials causes problems. The glaze should have a greater expansion than the underlying glass so that as the container cools from the firing process, the glass container develops compressive stress at the glaze–glass interface, rather than tensile stress. Glass is much stronger in compression than in tension. The glaze develops fine cracks or a crazed appearance during cooling, but the underlying glass will not be significantly damaged.

Ceramic glazes are used in ampuls to introduce a controlled-break site. A band of paint is applied at the constriction of the ampule where controlled breakage is desired, so the contents can be withdrawn. The band is used to make Colorbreak ampuls, and its function is to act as a stress concentrator when bending stress is applied to the ampul to break off the stem for product withdrawal. Very consistent ampul break forces are achieved by the use of ceramic bands.

Interior Surface Treatments (4)

Sometimes forming deposits become fused onto the glass surface and are difficult to remove, in effect compromising the durability of the interior surface. These effects are overcome by chemical neutralization of these deposits through surface treatment processes. At the same time, the intrinsic ability of a glass surface to withstand attack by aggressive products is also improved. Thus, there is a two-fold benefit in treatment processes for containers made from tubing: to remove the residual forming deposits and to improve the basic durability of the glass surface. These benefits are derived concurrently during treatment. Blow-molded containers, although not subject to the forming deposit problem, can also benefit from surface treatment.

If an aggressive product of pH 8 and above is to be packaged in a borosilicate container, surface treatment is required. Otherwise, the glass is attacked by the product, resulting in contamination by both soluble and insoluble reaction products. The latter are manifested by entities variously called flakes, shimmers, etc. These flakes are essentially silica that has been stripped off the surface by the attack on the glass. Their presence is direct evidence of excessive attack. Proper surface treatment enhances resistance to attack and results in a glass container that can contain products of pH 8 and higher without being damaged.

The basis of all treatment processes is the removal of alkali from the glass surface, resulting in improved resistance to attack by aqueous solutions. Alkali or sodium removal accomplishes this by greatly hindering the ion exchange process responsible for glass attack. Exchange of sodium ions in the glass for hydrogen ions in solution results in a pH rise in the solution; this can accelerate attack on the basic glass structure. If hydrogen ions cannot readily leave the solution because there are very few labile sodium ions with which to exchange, there will be little pH rise and, hence, little attack.

A common means of removing surface sodium is by reaction with sulfur dioxide in the presence of oxygen or by reaction with sulfur trioxide. The reaction product is sodium sulfate.

Surface treatment of blow-molded containers consists of several stages. As the freshly formed bottle leaves the mold and before it enters the annealing lehr or oven, it is still high in temperature. The bottle is filled with one or several of the following gaseous mixtures: sulfur trioxide, sulfur dioxide and oxygen, or 1,1-difluoroethane. If only moderate treatment is desired, one step suffices. The reaction of these gases with surface sodium starts immediately because of the glass temperature and

continues as the bottle enters the annealing process at its elevated temperatures. The reaction product of sodium sulfate is clearly seen in the cool bottle as a whitish haze on the inside surface just prior to packing into cartons. It is easily removed by subsequent washing processes. Blow-molded bottles treated by both of these steps can achieve high durability. These two methods, however, are restricted to large containers with relatively wide openings. Smaller containers made from tubing with much more restricted entry must be handled in a different way.

The effective treatment of containers made from tubing is a much more crucial issue because of the adverse effects of residual forming deposits and because the high pH products are usually packaged in small volume ampuls and vials made from tubing. The same basic treatment scheme is used, that of reacting the surface sodium with a sulfur compound at elevated temperatures. A 3% ammonium sulfate solution is injected into the container just prior to entering the annealing lehr; the volume injected is several tenths of a milliliter. The ammonium sulfate decomposes during the annealing process, with temperatures of 600–650°C being typical. The solution is thought to decompose, resulting in the formation of sulfuric acid vapors or possibly sulfur trioxide, which react with the surface sodium and any residual forming deposits, giving the characteristic sodium sulfate haze.

Containers given an effective surface treatment show a pronounced improvement in chemical inertness. Products packaged in such containers remain unaffected for long periods of time. The improvement of the inside surface, resulting from the surface treatment, is permanent and is not destroyed even by repeated autoclaving.

An additional reason for sulfur treating the interior surface of bottles is to improve the durability of soda-lime glass bottles. Normally, the surface inertness of soda-lime glass does not approach that of borosilicate. Sulfur treatment of a soda-lime surface can improve this situation to the point where products not normally considered for soda-lime containers can be packaged in them. The reason for choosing a treated soda-lime bottle for a mild product rather than a borosilicate bottle is based on economics, as soda-lime bottles are less expensive than borosilicate. It should be noted that this approach is used primarily for blow-molded bottles. There is compendial recognition and control of this, using treated soda-lime bottles in this way. Suffice it to say for the present that these bottles are known as Type-II bottles, according to the *United States Pharmacopeia* (USP). The USP and other methods of test and classification of glass for pharmaceutical products are discussed later.

Putting aside the question of testing and classifying Type-II bottles for the moment, it is of interest to consider test methods that determine the effectiveness of interior surface treatment of borosilicate containers made from tubing. It was stated earlier that a measure of durability, or inertness, is the pH rise of a contained solution. There are several commonly used ways of determining this. These methods are based on the pH rise of a water solution in the container after it has been autoclaved at 121°C for 60 min. The pH rise can be evaluated by titrating the solution with dilute acid in the presence of an indicator to a neutral end point. Another way is to include an indicator in the original water fill, autoclave, and observe the color change indicative of pH change. An example of this method uses bromothymol blue indicator adjusted to an initial pH of 5.8–6. The color of the indicator after autoclaving is compared to a series of standards having a range of pH up to at least 7.5 and the pH rise estimated. The autoclave cycle time and temperature used for these tests is that of the *Water Attack Test* as set forth in the USP described later in this chapter.

A solution autoclaved in a well-treated container consumes very small amounts of dilute acid upon titration or shows very small pH rise by color change of the indicator. Actual values of acid required, or pH rise, depend on various factors, including container size, as it controls the interior surface area-to-solution volume ratio (4).

Classification of Glass and Glass Containers—Compendial Perspective

The chemical specifications of glassware was first contained in USP XII in which specifications of glassware as containers for injections were provided. In subsequent revisions changes appeared and definitions of four types of glassware are described in USP XIX (11, 12).

Glass containers for pharmaceutical use are glass articles in direct contact with pharmaceutical preparation. In addition to the USP, the *European Pharmacopoeia* (EP) and other pharmacopeias have grouped glass containers suitable for packaging pharmacopeial preparations into the four different classifications specified in USP XIX up to USP 24 (13). The classes are based on the degree of chemical or hydrolytic resistance of these glasses to water attack. The degree of attack is determined by the amount of alkali released from the glass under the influence of the attacking medium under conditions specified. The quantity of alkali used is extremely small in some cases. These tests designs and glass classification are described from USP 24–NF 19

under section <661> *Containers* (13). These tests are designed to be conducted in areas relatively free from fumes and excessive dust.

Glass Types

The *USP* and *EP* have provided similar classifications that are summarized below.

Type I glass containers

Type I glass containers are comprised of a borosilicate glass with about 80% SiO_2 and 10% B_2O_3 and smaller amounts of Al_2O_3 and Na_2O . It is inert and has the lowest coefficient of thermal expansion. It is least likely to crack when a sudden temperature differential occurs. It is commonly used to make ampuls and vials for parenteral use. It is used for solutions that can dissolve basic oxides to cause an increase in pH that could alter the efficacy or potency of the drug (5).

USP describes Type I glass as:

Highly resistant borosilicate glass, and usually used for packaging acidic and neutral parenteral preparations. Also, where stability data demonstrates their suitability, Type I are used for alkaline parenteral preparations (13).

EP describes Type I glass as:

Neutral glass with high hydrolytic resistance due to the chemical composition of the glass itself. Type I are suitable for all preparations whether or not for parenteral use and for human blood and blood components (14).

Type II glass

A dealkalized form of soda-lime glass with higher levels of Na_2O and CaO . It is less resistant to leaching than Type I but more than Type III. However, to make Type II and other types more resistant to leaching, the surface can be treated with SO_2 to convert surface oxides present to soluble salts that are then washed off. This surface treatment is effective for containers used once and those repeatedly exposed to heat. Type II has a lower melting point than Type I and, therefore, is easier to fabricate. It has a higher coefficient of thermal expansion, and is used in solutions that can be buffered to maintain a pH below 7 (5).

[*USP*] Soda-lime glass that is suitably dealkalized and is used for packaging acidic and neutral parenteral preparations, and also where stability data demonstrates their suitability, is used for alkaline parenteral preparations (13).

[*EP*] Soda-lime silica glass with high hydrolytic resistance resulting from suitable treatment of the surface. These containers are suitable for acidic and neutral, aqueous preparations for parenteral use (14).

Type III glass

A soda-lime glass containing same amount of sodium and oxide levels as in Type II but contains more leachable oxides of other elements. And because of its high reactivity, it is used to package anhydrous liquids and other dry products (5).

[*USP*] These are soda-lime glass containers that are usually not used for parenteral preparations, except where suitable sensitivity test data indicates that Type III is satisfactory for the parenteral preparations that are packaged therein (13).

[*EP*] These are soda-lime glasses with only moderate hydrolytic resistance. They are suitable for nonaqueous preparations for parenteral use, for powders for parenteral use, and for preparations not for parenteral use (14).

Type IV or NP glass

[*USP*] These are general purpose soda-lime glass. They are intended for packaging nonparenteral articles, i.e., those intended for oral or topical use (13).

[*EP*] These are soda-lime silica glass with low hydrolytic resistance. These are suitable for solid preparations that are not for parenteral use and for some liquid or semi-solid preparations that are not for parenteral use (14).

Tests

These glass containers for pharmaceutical use have to comply with relevant tests such as tests for hydrolytic resistance for *EP* (14), and tests chemical resistance for *USP* (13). The test procedure and methods are slightly different for each of the pharmacopeias. However, this article will emphasize the test procedure provided in the *USP 24-NF 19*.

For the four types of glasses, there are designated relevant test types and expected limits. These are provided in Table 3.

USP has provided procedure and test requirements for three types of tests. These are the *Powdered Glass Test*, the *Water Attack* test, and the *Arsenic* test. These tests,

Table 3 USP glass types, test type, and limits

Glass type	Test type	Limits	
		Size ^a (ml)	ml of 0.020 N Acid
I	Powdered glass	All	1.0
II	Water attack	100 or less	0.7
		Over 100	
III	Powdered glass	All	8.5
NP	Powdered glass	All	15.0

^aSize indicates the overflow capacity of the container.

Apparatus, and Reagents for the tests are described below (13).

Apparatus used for these tests^a

Autoclave: An autoclave capable of maintaining a temperature of 121 ± 2.0°C, equipped with a thermometer, a pressure gauge, a vent cock, and a rack adequate to accommodate at least 12 test containers above the water level is used.

Mortar and pestle: A hardened-steel mortar and pestle, made according to the specifications in the accompanying illustration.

Other equipment: Sieves, about 20.3-cm (8-inch), made of stainless steel including the Nos. 20, 40, and 50 sieves, along with the pan and cover (see *Openings of Standard Sieves* (811)), 250-ml conical flasks made of resistant glass aged as specified, a 900-g (2-lb) hammer, a permanent magnet, a desiccator, and an adequate volumetric apparatus are used.

Reagents used for these tests^b

High-purity water: The water used in these tests has a conductivity at 25°C, as measured in an in-line cell just prior to dispensing, of not greater than 0.15 μs per cm (6.67 Megohm-cm). There must also be an assurance that this water is not contaminated by copper or its products (e.g., copper pipes, stills, or receivers). The water may be prepared by passing distilled water through a deionizer cartridge packed with a mixed bed of nuclear-grade resin, then through a cellulose ester membrane having openings not exceeding 0.45 μm. Do not use copper tubing. Flush the discharge lines before water is dispensed into test vessels. When the low conductivity specification can no longer be met, replace the deionizer cartridge.

Methyl red solution: Dissolve 24 mg of methyl red sodium in purified water to make 100 ml. If necessary,

neutralize the solution with 0.02 N sodium hydroxide or acidify it with 0.02 N sulfuric acid so that the titration of 100 ml of High-purity water, containing 5 drops of indicator, does not require more than 0.020 ml of 0.020 N sodium hydroxide to effect the color change of the indicator, which should occur at a pH of 5.6 (13).

Powdered glass test for Types I, II, and NP glasses^c

Rinse thoroughly with purified water six or more containers selected at random, and dry them with a current of clean, dry air. Crush the containers into fragments about 25 mm in size, divide about 100 g of the coarsely crushed glass into three approximately equal portions, and place one of the portions in the special mortar. With the pestle in place, crush the glass further by striking three or four blows with the hammer. Nest the sieves, and empty the mortar into the No. 20 sieve. Repeat the operation on each of the two remaining portions of glass, emptying the mortar each time into the No. 20 sieve. Shake the sieves for a short time, then remove the glass from the Nos. 20 and 40 sieves, and again crush and sieve as before. Repeat again this crushing and sieving operation. Empty the receiving pan, reassemble the nest of sieves, and shake by mechanical means for 5 min or by hand for an equivalent length of time. Transfer the portion retained on the No. 50 sieve, which should weigh in excess of 10 g, to a closed container, and store in a desiccator until used for the test.

Spread the specimen on a piece of glazed paper, and pass a magnet through it to remove particles of iron that may be introduced during the crushing. Transfer the specimen to a 250-ml conical flask of resistant glass, and wash it with six 30-ml portions of acetone, swirling each time for about 30 s and carefully decanting the acetone. After washing, the specimen should be free from agglomerations of glass powder, and the surface of the grains should be practically free from adhering fine particles. Dry the flask and contents

^cFrom USP 24–NF 19, © USP.

for 20 min at 140°C, transfer the grains to a weighing bottle, and cool in a desiccator. Use the test specimen within 48 h after drying.

Procedure

Transfer 10.0 g of the prepared specimen, accurately weighed, to a 250-ml conical flask that has been digested (aged) previously with High-purity water in a bath at 90°C for at least 24 h or at 121°C for 1 h. Add 50.0 ml of High-purity water to this flask and to one similarly prepared to provide a blank. Cap all flasks with borosilicate glass beakers that previously have been treated as described for the flasks and that are of such size that the bottoms of the beakers fit snugly down on the top rims of the containers. Place the containers in the autoclave, and close it securely, leaving the vent cock open. Heat until steam issues vigorously from the vent cock, and continue heating for 10 min. Close the vent cock, and adjust the temperature to 121°C, taking 19–23 min to reach the desired temperature. Hold the temperature at $121 \pm 2.0^\circ\text{C}$ for 30 min, counting from the time this temperature is reached. Reduce the heat so that the autoclave cools and comes to atmospheric pressure in 38–46 min, being vented as necessary to prevent the formation of a vacuum. Cool the flask at once in running water, decant the water from the flask into a suitably cleansed vessel, and wash the residual powdered glass with four 15-ml portions of High-purity water, adding the decanted washings to the main portion. Add 5 drops of Methyl Red Solution, and titrate immediately with 0.020 *N* sulfuric acid. If the volume of titrating solution is expected to be less than 10 ml, use a microburet. Record the volume of 0.020 *N* sulfuric acid used to neutralize the extract from 10 g of the prepared specimen of glass, corrected for a blank. The volume does not exceed that indicated in Table 1 for the type of glass concerned (13).

Water attack at 121°C for Type II glasses^d

Rinse thoroughly twice 3 or more containers, selected at random, with high-purity water.

Procedure: Fill each container to 90% of its overflow capacity with High-purity water, and proceed as directed for *Procedure* under *Powdered Glass Test*, beginning with “Cap all flasks,” except that the time of autoclaving shall be 60 min instead of 30 min, and ending with “to prevent the formation of a vacuum.” Empty the contents from 1 or more containers into a 100-ml graduated cylinder, combining, in the case of smaller containers, the contents of several containers to obtain a volume of 100 ml. Place the pooled specimen in a 250-ml conical flask of resistant

Fig. 4 Typical light transmission of clear and amber borosilicates.

glass, add 5 drops of Methyl Red Solution, and titrate, while warm, with 0.020 *N* sulfuric acid. Complete the titration within 60 min after opening the autoclave. Record the volume of 0.020 *N* sulfuric acid used, corrected for a blank obtained by titrating 100 ml of High-purity water at the same temperature and with the same amount of indicator. The volume does not exceed that indicated in Table 1 for the type of glass concerned (13).

Arsenic test^d

For the *Test Preparation*, 35 ml of the water from one Type I glass container or, in the case of smaller containers, 35 ml of the combined contents of several Type I glass containers, are used and prepared as directed for *Procedure* under *Water Attack at 121°C* and the procedure described for *Arsenic* test in *USP 24–NF 19* general chapter <211> *Arsenic* is then followed. The limit provided for this test is 0.1 ppm.

Light transmission test^d

In addition to the above-mentioned tests, compendial limits are provided for light transmission for colored light protecting glass containers. These containers intended to provide protection from light or supplied as “light Resistant” are expected to meet the requirements for *Light transmission* in this section. Light Transmission characteristics of typical clear and amber borosilicates are shown in Fig. 4.

In this test, a spectrophotometer of suitable sensitivity is used to a cut section of the glass container. The transmittance of the section is measured, and the observed light transmission is not expected to exceed the limits provided in Table 4.

^dFrom *USP 24–NF 19*, © USP.

Table 4 Limits for glass types I, II, and III

Normal size (in ml)	Maximum percentage of light transmission at any wavelength between 2990 and 450 nm	
	Flame-sealed containers	Closure-sealed containers
1	50	25
2	45	20
5	40	15
10	35	13
20	30	12
50	15	10

(From *USP 24–NF 19*, © USP.)

These methods of testing glass are basically similar to other compendial limits and other standards on glass such as those in International Organization for Standardization (ISO), German DIN, and the ASTM. The expected limit and test result expectations and procedures may vary for each standard of compendial method.

There are differences in testing glass as a container compared to glass as a material (glass-grain tests). The glass surface area-to-solution volume ratio is higher in grain tests, resulting in higher concentrations of glass constituents in solution after autoclaving. This facilitates solution analysis and differentiation between glasses. The other major difference is the presence of forming deposits, in the case of containers made from tubing, which influences test results. Blow-molded container test results are not affected by deposits.

SUMMARY

Glass as a packaging material has many advantages. Glass provides:

- Total impermeability to gaseous environmental contaminants
- Total impermeability to loss of essential volatile ingredients by diffusion through the container walls
- Excellent clarity and attractive sparkle
- Ease of cleaning and sterilizing with heat
- Resistance to attack by all liquids except HF and other caustic products
- A variety of shapes and it can accept a wide variety of closure types
- Ease of filling, closing, unscrambling, labeling, and cartoning

- Good compressional strength to allow efficient storage, especially allowing cartons of glass to be stacked high in warehouse
- Ease of hot-filling

Glass has disadvantages that include:

- Breakage—when it breaks, it shatters into numerous sharp fragments
- Weight—with a density of 2–2.5 g/ml, along with brittle character thick container walls, they become quite heavy
- Cost—in some cases, they are very expensive because of their weight and the type of fabrication involved (5)

GERIATRIC DOSING AND DOSAGE FORMS

Cheryl A. Wiens

University of Alberta, Edmonton, Alberta, Canada

Carol A. Borynec

University Hospital, Edmonton, Alberta, Canada

DEMOGRAPHICS

The word *geriatric* refers to individuals who are over age 65 years. This has been described as the most heterogeneous population because it constitutes fit, physiologically healthy patients to extremely frail, debilitated patients in long-term care facilities (LTCF).

Currently, greater than 12% of the population in the United States (1) is aged 65 years and over. This population is prescribed approximately one-third of all prescription medications (2). On average, geriatric patients use four to five medications, and greater than 50% use over-the-counter (OTC) medications. The use of medications is even higher in the LTCF population.

The elderly are also more likely to suffer from chronic disease and multiple disease states and therefore receive long-term treatment with medications. Considering the high medication utilization of geriatric patients, it is pertinent to focus on geriatric dosing and dosage forms.

PHYSIOLOGIC CHANGES WITH AGING

Although development of disease is not considered normal with aging, there are a number of physiological changes which can predispose the elderly to developing illness (Table 1). Many of the age-related physiological changes have been reviewed previously (3, 4). Because of the physiological changes that occur with the aging process, there are changes in the pharmacokinetics and pharmacodynamics of medications.

PHARMACOKINETICS

Pharmacokinetics refers to how the body handles medications. As the body changes with age, its ability to absorb, distribute, and break down drugs can change significantly. Unfortunately, in some cases, it is difficult to

predict how significantly aging will affect some people, thus, dosing changes alone cannot be based solely on age. Pharmacokinetics can be broken down into four processes: 1) absorption (of the medication through the gastrointestinal tract, a mucous membrane, or the skin); 2) distribution (of the medication throughout the body); 3) metabolism (most often through the liver); and 4) elimination (most often through the kidneys).

Absorption

There appears to be little change in absorption of medications in the elderly (3, 5, 6). Dry skin may decrease absorption of topically applied medications. A decrease in stomach acid secretion may affect absorption of certain medications when given orally; however, this is not consistent for all geriatric patients. Other changes that may contribute to altered absorption may include dietary changes, a decrease in salivary secretion, or use of dentures (3). Absorption is generally dependent on the concomitant disease states of the patient (3). For example, if a patient had congestive heart failure, with significant congestion of the gastrointestinal (GI) tract, then less medication and nutrients would be absorbed through the GI tract. The decreased absorption is not related to age but results from concomitant systemic or GI diseases.

Distribution

Physiological changes owing to the aging process will result in an increase in lipid mass and a decrease in lean body mass (3, 5, 6). Fat-soluble medications may distribute more widely and remain in the body longer in an elderly patient, whereas water-soluble medications have a smaller volume of distribution because of decreased lean mass.

Distribution of medications is also determined by protein binding in the serum (6, 7). The most common protein is albumin, which binds predominantly acidic drugs such as phenytoin. Another common protein is α -1 acid glycoprotein, an acute-phase reactant, which has a higher affinity for basic drugs such as lidocaine. The most

Table 1 Age-related physiological changes in the elderly

Organ system	Change
Body composition	↓ lean body mass ↑ body fat ↓ body water
Cardiovascular	↓ cardiac output ↓ stress response (β -response blunted)
Central nervous system	↓ peripheral conduction velocity ↓ weight, volume of brain
Endocrine	↓ hormonal secretions menopausal changes ↑ incidence diabetes, thyroid atrophy
Gastrointestinal	↓ secretions ↓ rate of stomach emptying ↓ rate of intestinal transit time ↓ liver volume and blood flow
Genitourinary	Atrophy vagina, prostate
Immune	↓ cell-mediated immunity
Pulmonary	↓ elasticity, chest wall compliance ↓ alveolar surface
Renal	↓ nephrons ↓ creatinine clearance ↓ renal blood flow ↓ glomerular filtration rate (GFR)
Sensory changes	↓ accommodation of lens of eye
Skeletal	↓ skeletal bone mass
Skin and hair	↓ hydration of skin ↓ in dermal thickness

↓ Indicates decrease; ↑ indicates increase.

important consideration for protein levels when considering drug distribution is to take into account the health status of the individual. An elderly patient may experience only a small decline in protein levels owing simply to age. However, chronic inflammatory disease states may significantly increase the levels of α -1 acid glycoprotein, thereby decreasing the free level of medication in the blood stream. When considering albumin, it is important to take into account chronic disease states and nutritional status. Poor nutritional intake will result in a lower level of albumin and, therefore, a higher free level of drug. In most cases a higher free level of drug does not result in a clinically significant response (because the liver most often compensates for the increased drug levels and simply metabolizes the excess levels with hepatic reserve); however, this may be quite important for medications with a narrow therapeutic index. Medications such as warfarin require very careful monitoring to maintain the International Normalized Ratio (INR) within a very narrow

therapeutic range. In this case, if warfarin increases even slightly, the response could be far greater than expected.

Second, tissue protein binding of medication can affect drug disposition in the elderly patient. For example, amiodarone binds strongly to tissue proteins, which greatly increases its volume of distribution. In the elderly or chronically ill patient, tissue proteins may change or decline, which can also affect the serum levels of medications.

Finally, free drug levels may be affected by interaction with other medications, which may cause displacement of a drug off the protein. Considering that the elderly are taking more medications, they are more likely to experience protein-displacement drug interactions. However, protein-displacement interactions are not considered as clinically significant as metabolism interactions.

Metabolism

Liver blood flow decreases with age, but overall it does not appear to affect the metabolizing capacity of the hepatocytes. Medications that are dependent on liver blood flow for break down may have a somewhat delayed metabolism (3, 5, 6). There is some decline in phase I metabolism but not necessarily in phase II metabolism (5). Phase I metabolism involves the oxidation/reduction reactions commonly needed to metabolize medications. Phase II reactions, including conjugation reactions, appear to remain grossly intact in the elderly. This means that medications that are metabolized by phase II metabolism are preferred over agents that require phase I metabolism. In elderly patients who appear frail or suffer from chronic disease, both phase I and phase II metabolisms may show a decline. However, age alone does not appear to cause a decline in phase II metabolism. It is important to consider the chronic disease states or lifestyle factors, such as diet, smoking, and ethanol intake, in predicting the metabolizing capability of a patient (3, 5, 6). Patients who have poor diet and negative lifestyle factors such as cigarette smoking and high consumption of alcohol are less likely to have hepatic metabolizing reserve and are more likely to suffer adverse reactions from medication because of relative overdosing (or incapacity to metabolize a standard dose of medication). Although the elderly may have little change in their metabolizing capacity owing to age only (6) applying the above principles to dosing is recommended.

Elimination

Renal function generally decreases with age (3, 6). It is not possible to predict which patients will not experience a decline in renal function, even though it has been estimated that up to 30% of the elderly have no change in their renal

function. The most commonly used nomogram to predict renal function is the Cockcroft–Gault equation (8), which factors in age, causing a decline in renal function. Unfortunately, this equation was not originally validated in an elderly, frail, or female population. Furthermore, predicting renal function is most difficult in frail patients. Careful monitoring for response to the medication and side effects is necessary to avoid an excessive dosage. It is also difficult to predict renal function in these clinical situations: malnourished patients who have low muscle mass and, therefore, low serum creatinine; patients who are missing a limb; and individuals who do not have stable renal function (creatinine not having reached steady state).

Medications that are eliminated renally should be given in a reduced dosage or given less frequently than in younger patients. However, the exact dosing cannot be predicted accurately in many subpopulations of the elderly including the very old (>85 years) nor in the frail patients. In these populations, it is appropriate to monitor drug response based on clinical improvement or signs and symptoms of toxicity (3, 5, 6). Monitoring drug levels at steady state may also be necessary.

PHARMACODYNAMICS

Pharmacodynamic changes in the elderly are also documented (5, 9); however, they are not as well-researched or defined as are pharmacokinetic changes. Pharmacodynamics refers to the change in response to the medication. Possible mechanisms include (9):

- Change in receptor density
- Change in receptor affinity and receptor characteristics
- Postreceptor alterations (change in transduction signal coupling or amplification)
- Desensitization of receptors
- Altered negative feedback responses
- Target tissues exhibit intrinsic change

These alterations in homeostatic function can result in significant impairment or adverse consequences if these changes are not accounted for while prescribing certain medications (Table 2).

Changes in Sensitivity

The elderly are more likely to be sensitive to a number of different classes of medication because of changes in pharmacodynamics (5, 9–11). It is very important to monitor and adjust the dosage of certain classes of medications in the elderly owing to their increased or decreased sensitivity (Table 3).

ADVERSE DRUG REACTIONS (ADR) / ADVERSE DRUG EVENT (ADE)

As Lamy (12) has pointed out, there is much debate regarding the definition of an adverse drug reaction (ADR) or an adverse drug event (ADE). An ADR has been defined by the World Health Organization (WHO) as a noxious, unintended effect of a drug that occurs in doses normally used in humans for the diagnosis, prophylaxis, or treatment of disease. An ADR also can be defined as an undesirable effect of drug therapy beyond its anticipated therapeutic effects occurring during clinical use. An ADE is defined as a noxious and unintended patient event caused by a drug (e.g., laboratory abnormalities, symptoms, signs, etc.). In the outpatient geriatric population, approximately 30% will experience an ADR and are responsible for approximately 10–20% of hospital admissions (12–14). In hospitalized patients, the incidence of an ADR or ADE is estimated to be 10–25% (15). Studies have found that the majority of events are avoidable (12), and unfortunately, many patients (estimated to be one-third) do not fully recover from the ADR.

ADRs are also a concern because of the associated costs, primarily related to hospitalization. ADRs increase length of stay and risk of mortality, which overall increase costs of the ADR treatment. The elderly with ADRs also visit their physician more frequently than elderly patients who are not experiencing ADRs (16). The elderly patient may not bring up concerns with healthcare professionals (12) and may go on to accept the ADR as a part of normal treatment. The incidence of ADR therefore may be significantly underreported in the elderly population.

Assessing the risk of ADRs in the elderly can be difficult because most clinical trials exclude the elderly because of comorbidities or age. There is also a bias in prescribing, thus, elderly patients at risk of experiencing adverse effects from a drug may not even be exposed to the medication. This provides an underestimate of the true incidence of ADRs in an entire population who may take the medication (5, 12, 17).

The risk of experiencing an ADR is related to the diagnosis, types of medications prescribed, and the number of drugs used (5, 12–14, 17). The most significant factor is multiple drug use and is related to number of coexisting diseases. When the number of medications is decreased, it has been shown that ADRs also decrease (12). It appears that the number of medications increases the risk of ADR exponentially (14).

It is debatable if age alone is an independent risk factor for ADR; however, the elderly are more susceptible to ADRs because of physiological changes resulting in

Table 2 Altered homeostatic mechanisms in the elderly

Altered function	Mechanism	Examples of drugs
Anticoagulation	Poor hepatic production of coagulation factors	Anticoagulants
Arrhythmias	Poor dietary intake	Thrombolytics
Higher cognitive function	Cardiac hypersensitivity	Antiarrhythmic medication
	Central cholinergic transmission	Central anticholinergics
	Neuronal loss	Stimulants β -agonists
	Receptor downregulation	
Orthostasis	Blunting of β response (no tachycardia)	Blood pressure medications
	Changes in vascular tree	Tricyclic antidepressants
	Changes in autonomic nervous system	Antipsychotics
	Receptor down regulation	Diuretics
Postural control	\downarrow D2 receptors in the striatum	Sedative hypnotics
	\uparrow Risk of sway	
Tardive dyskinesia	Impaired dopamine-synthesizing neurons	Traditional antipsychotics
Thermoregulation	Poor temperature-regulating mechanisms: \downarrow shivering \downarrow metabolic rate \downarrow vasoconstriction \downarrow thirst response \downarrow subjective awareness of temperature	Long-term antipsychotic therapy Medications affecting awareness, mobility, muscular activity, vasoconstrictor mechanisms CNS medications Phenothiazines Barbiturates Benzodiazepines Tricyclic antidepressants Narcotics Alcohol
Visceral muscle function	Visual disturbances (pupillary autonomic responses) Bladder instability (bladder capacity, detrusor contractions) Intestinal motility decreased	Anticholinergic medications

\downarrow Indicates decrease; \uparrow indicates increase.

Table 3 Medications affected by changes in sensitivity

Medication (class)	Altered effect	Recommendation
ACE-I	Greater sensitivity to BP reduction Increased risk hyperkalemia	Lower initial dose
Antiarrhythmics (class I)	Longer elimination $t_{1/2}$	Lower initial dose
Antiarrhythmics (class III)	Longer elimination $t_{1/2}$	Lower initial dose
Anticholinergics	Increased sensitivity to anticholinergic effects, increased risk confusion	Avoid if possible
Antipsychotics	Greater risk orthostasis and movement disorders	Use lowest initial dose when necessary
		Lower initial dose
β -blockers	Low potency agents—more likely to cause confusion	
Benzodiazepines	Greater sensitivity to BP reduction Longer elimination $t_{1/2}$ Greater sensitivity to sedating effects	Lower initial dose Use shorter-acting hydrophilic agents such as lorazepam, oxazepam
Corticosteroids	Increased sensitivity to GI complications	Lower initial dose
Digoxin	Increased risk osteoporosis Decreased volume of distribution	Minimize duration of therapy if possible
Diuretics	↓ responsiveness owing to decline in renal function	Lower loading dose
NSAIDs	Greater risk of GI complications	Lower maintenance dose Enhanced monitoring of renal function, electrolytes
		Used only after acetaminophen for OA
Opioids	Increased sensitivity to effect Longer elimination $t_{1/2}$	Recommended with GI-protective agent or use a COX-II inhibitor
SSRIs	Longer elimination $t_{1/2}$	Lower initial dose
Tricyclic antidepressants	Greater sensitivity to anticholinergic effects, arrhythmic effects	Avoid using fluoxetine
Warfarin	Increased sensitivity to anticoagulant effect	Preference for desipramine, nortriptyline (better tolerated secondary amines)

ACE-I, indicates angiotensin-converting enzyme inhibitor; SSRI, selective serotonin receptor inhibitor; NSAID, nonsteroidal anti-inflammatory drug; OA, osteoarthritis.

altered pharmacokinetics or pharmacodynamics. Some studies have shown that when controlling for confounders such as clinical status of the patient, number of medications, and length of hospital stay, age alone does not predict ADRs (12, 17).

It is important to note that withdrawal of medications may also lead to ADR (18). Certain settings (e.g., LTCF) encourage prescribers to remove medications, some of which may have been used by the patient for many years. If the withdrawal of therapy is not appropriate or is done too quickly, this may cause ADR for the patient (18, 19).

The most common drugs involved in ADRs are cardiovascular medications, aspirin, NSAIDs, and psychotropic agents. However, it should be noted that these are also the most commonly used medications in the elderly (14).

The prevention of ADRs in the elderly has been inadequately studied. Considering that the majority of ADRs are type A (dose-related) it would appear that most ADRs in the elderly could be prevented. Additional study on this subject is necessary to determine the most effective interventions in decreasing the incidence of ADRs in the elderly. A review by Atkin (14) has addressed studies that suggest improvements such as better history-taking and record-keeping by physicians to minimize the number of medications used by patients. Other suggestions include requesting that patients always bring their medications to medical appointments and using medications that would be considered lower risk in this population.

There are a number of different ways to assess and identify an ADE. Listed below are a number of tables that will assist in interpreting signs or symptoms that may indeed be an adverse drug event. Table 4 identifies disease states that may contribute to similar symptoms that may be misdiagnosed as an ADE. Other syndromes that are most commonly associated with toxicity or side effects from specific medications are shown in Table 5. Finally, medication classes that most commonly causes ADEs in the elderly are presented in Table 6.

Falls

Falls are common in the elderly and are often multifactorial (20–22). There is a concern about patients who fall because the complications are significant. Complications include fractures, soft tissue injuries, immobilization and hospital-acquired illness, institutionalization, and even death from additional complications such as pneumonia (20). It is difficult to determine the percentage of patients who fall because many falls do not result in injury and are never reported.

The cost involving treatment of falls is staggering (21, 22), including costs for hospitalization and acute

care, rehabilitation, and institutionalization, if necessary. It has been estimated that falls cost \$12.6 billion in lifetime expenses for persons older than 65 years of age. There is also a tremendous emotional impact on the patients, causing many patients to lose their sense of security and to remain housebound.

Although certain illnesses contribute to falls, medications have been shown to cause falls independent of other factors. The most commonly offending drugs are benzodiazepines because they have been shown to increase falls and hip fractures (23). An association between the dose (the higher the dose, the more likely the fall), duration of use, and type of benzodiazepine (e.g., long-acting medications) has also been reported. Other classes of medications that increase the risk of falls include tricyclic antidepressants, SSRIs, and opioid analgesics (23, 24).

It may be entirely appropriate to continue using these medications if they are prescribed. To ensure safe drug use, patients should be cautioned about the risk of falling and encouraged to use extra precautions. High-risk medication should be administered only when needed, rather than on a scheduled basis, because this will hopefully decrease the overall dose. In the elderly, a short-acting phase II metabolized benzodiazepine such as oxazepam or lorazepam would be preferred if a benzodiazepine is necessary.

Delirium

Drug-induced changes in cognition are common and disturbing ADRs for both the patient and the patient's family or caregiver. Delirium is commonly reported on hospital admission (approximately 10–15% of elderly patients meet criteria for diagnosis of delirium) (25, 26). There is also a significant occurrence of delirium in elderly patients undergoing various types of surgery, including general surgery open heart surgery and hip fracture repair (may be as high as 50%) (25, 26). The outcome after diagnosis of delirium is poor. At 1 month, the mortality has been shown to be as high as 14%, and at 6 months mortality is 22%. If the patient survives, change in cognitive symptoms may last for 3 months postdischarge. Furthermore, these patients are at an increased risk for other complications, including prolonged hospital stay, functional decline, and institutionalization.

Medications may cause, or at least exacerbate, delirium in many patients. Polypharmacy has been shown to be a risk factor for delirium. There are a number of different types of medications that may cause delirium. Many have anticholinergic properties, whereas others have a yet-unknown mechanism for causing delirium (Table 4). Patients who present with acute changes in mental status

Table 4 Presenting symptoms and associated adverse drug events (ADE)

Symptom	Underlying condition	Drug cause of ADE
Disturbed mental status/delirium	Hypoglycemia Hypothyroidism B12 deficiency Uremia	Anticholinergic medications and/or properties Antipsychotics Antihistamines Antiparkinsonian agents Antispasmodics Ophthalmic preparations OTC sleep/allergy medications Tricyclic antidepressants Other medications Analgesics/NSAIDs Anticonvulsants Corticosteroids (high dose) Digoxin H2 blockers Insulin Muscle relaxants Narcotics Psychotropics (anxiolytic, antidepressant, antipsychotic) Sedative/hypnotic Sulfonylurea
Depression	Hypercalcemia Hypo-hyperthyroidism	Hypnotics Amiodarone Lipid-soluble β -blockers
Fatigue	CHFGI bleed Anemia Hypothyroidism	Diuretics β -blockers Hypnotics Muscle relaxants
Falls/syncope	Structural CNS lesion Dehydration Hypokalemia Arrhythmias	Antiarrhythmics Levodopa Diuretics Antihypertensives TCA Sedatives Antipsychotics Hypoglycemics Alcohol

or delirium must be evaluated medically and should include a review of their medications. Typically, all medications should be discontinued and restarted only if considered life-saving at the time. Long-term chronic medications should be held because it is important to resolve delirium and attempt to identify which medications may be the offending agent (25–27).

Drug–Drug Interactions

Drug interactions are very common in the elderly, attributable in part to the high number of medications

prescribed in this population. Drug interactions are considered one type of adverse drug event and have been found to increase with the number of medications prescribed (28). Drug interactions are also a common cause of hospital admission (29).

The elderly are particularly susceptible to interactions because of the changes in physiology, multiple physician prescribing, increased use of OTC medications, nonadherence to complex regimens, and multiple disease states that complicate the handling of medications.

Medication interactions have been found to be poorly monitored. Medications are often necessary, and

Table 5 Common adverse effects

Adverse effect	Possible medications
Anticholinergic effects	Antihistamines
Delirium	Tricyclic antidepressants
Dry mouth	Medications for urge incontinence
Constipation	
Urinary retention	
Tachycardia	
Disturbed vision	
Blurring	See anticholinergic effects
Dry eyes	Glaucoma medications Ocular lubricants
Extrapyramidal effects	Antipsychotics
Tremor	Antiemetic (metoclopramide)
Pseudoparkinsonism	
Akathisia	
Sedation	Antipsychotics Sedative/hypnotics Tricyclic antidepressants Muscle relaxants
Orthostatic hypotension	Antihypertensives Diuretics Levodopa Tricyclic antidepressants

Table 6 Medication classes commonly affecting mobility in the elderly

Medication class	Mobility ADE
Antihypertensives	Postural hypotension
Antipsychotics	Postural hypotension Sedation Extrapyramidal effects Falls
Narcotics	Sedation Confusion ↓ coordination (falls)
Sedative/hypnotics	Sedation Weakness Confusion ↓ coordination (falls)
Tricyclic antidepressants	Postural hypotension Sedation Arrhythmias Falls

↓ Indicates decrease.

interactions can be handled in a manner in which the patient does not experience adverse effects and yet receives the benefit of appropriate medications.

There are various types of drug interactions. One classification is pharmacokinetic or pharmacodynamic interactions. Pharmacokinetic interactions describe an interaction with absorption, metabolism, or elimination. Medications can also displace each other through competitive protein binding. Many pharmacokinetic interactions result through competition or interaction at the cytochrome enzyme system called the CYP450 system (28). Numerous isozymes, or subtypes, have been discovered. Each isozyme is responsible for metabolizing specific medications. These isozymes may be inhibited or induced by certain disease states or by other medications. Pharmacodynamic interactions refer to additive or antagonistic activity or action of one medication on another. The study of pharmacokinetic interactions is often done in younger, healthy patients and may not reflect what commonly occurs in an elderly patient. It may also be difficult to predict the extent of the interaction; however, some studies have resulted in specific recommendations on how to adjust the dose of interacting medications.

Table 7 contains a list of drug classes and clinically significant drug interactions. This is not a comprehensive list, and the reader is referred to the appropriate chapter dealing with pharmacokinetic drug interactions.

Drug–Food Interactions

Table 8 lists commonly used drugs and potential food interactions. This is not a comprehensive list, but rather highlights many of the clinically significant food–drug interactions (30).

Recent concerns with food products include grapefruit juice, which has been shown interact with many different medications through the CYP450 3A4 isoenzyme. This may increase the levels of medication such as cyclosporine, dihydropyridine calcium channel blockers, midazolam, triazolam, and astemizole (31).

DRUG MANAGEMENT PROBLEMS IN THE ELDERLY

Adherence

Traditionally called compliance, the concept of not taking medication properly is now called nonadherence. However, these words are often used interchangeably. The documented rates range from 25 to 50% in the elderly (32). Intentional nondadherence, or consciously making a decision to not take the medications as prescribed, involves not taking the medication at all or using only

Table 7 Drug–drug interactions of commonly used medications in the elderly

Drug	Interacting drug	Mechanism/effect	Management
Analgesics NSAIDs	Warfarin	Increased risk of bleeding	Avoid use of NSAIDs while using warfarin
	Corticosteroids	Increased fluid retention; increased risk of GI bleeding	Avoid use of NSAIDs while using corticosteroids; use selective COX-II inhibitors if necessary
Opioids	Alcohol	Increased risk of CNS depression; respiratory depression	Avoid use of multiple CNS depressants; decrease doses of CNS depressants when used concomitantly
	Antipsychotics		
	TCA		
Acetylcholinesterase inhibitors	Sedative/hypnotics		
	Phenothiazine antipsychotics; tricyclic antidepressants; anticholinergic medications		
Acetylcholinesterase inhibitors (A.Ch.E.-I) (donepezil, tacrine, rivastigmine)	Bethanechol	Antagonize acetylcholine increasing effect of A.Ch.E.-I	Avoid use of anticholinergics when using A.Ch.E.-I
Donepezil	Succinylcholine	Additive cholinergic side effects (e.g., nausea, abdominal cramping)	Avoid use of bethanechol with A.Ch.E.-I
	Ketoconazole	Exaggerated muscle relaxation	Discontinue A.Ch.E.-I before surgery
Tacrine	Quinidine	Inhibited metabolism of donepezil	Monitor for donepezil toxicity; dose reduction not empirically necessary
	Fluvoxamine	Decreased metabolism of tacrine leading to increased levels of tacrine	Avoid use of interacting medications; monitor for signs of toxicity of tacrine
	Cimetidine		
	Quinolones		
Antibiotics Aminoglycosides	Theophylline	Inhibition of theophylline metabolism	Decrease dose of theophylline while using tacrine
	Diuretics	Increased risk of dehydration, renal impairment	Monitor renal function, hydration closely
	Cisplatin	Increased risk of nephrotoxicity	Monitor renal function closely
Quinolones	Vancomycin		
	Iron supplements antacids (aluminum-calcium-or magnesium-containing)	Impair absorption of quinolone	Avoid taking quinolone within 2 h of these medications
Ciprofloxacin	Theophylline	Reduced clearance of theophylline and caffeine; increased risk of CNS toxicity	Decrease dose of theophylline; avoid caffeine intake
	Caffeine		
Sulfonamides	Warfarin	Displacement of medications from protein binding sites; transient increase in drug levels and toxicity	Monitor for toxicity of displaced medications
	Sulfonyleurea		
	Phenytoin		
	Methotrexate		

(Continued)

Table 7 Drug–drug interactions of commonly used medications in the elderly (*Continued*)

Drug	Interacting drug	Mechanism/effect	Management
Isoniazid (INH)	Phenytoin	Inhibition of metabolism—increased toxicity of anticonvulsants	Monitor levels of anticonvulsants during INH therapy
	Carbamazepine	Increased risk of hepatotoxicity	Avoid use of ethanol during INH treatment
Anticonvulsants Phenytoin	Ethanol		Monitor for phenytoin toxicity; reduce dose as needed
	Amiodarone	Increased level of phenytoin	
	Cimetidine		
	Fluoxetine		
	Fluconazole		
	Ketoconazole		
	Carbamazepine	Decreased level of phenytoin	Increase dose of phenytoin to reach therapeutic blood level
	Rifampin		
	Theophylline		
	Isoniazid	Increased risk of hepatotoxicity	Monitor hepatic function closely while using this combination
Carbamazepine	Erythromycin	Increased levels, toxicity of carbamazepine	Monitor toxicity of carbamazepine; dosage may require reduction
	Cimetidine		
	Diltiazem		
Gabapentin	Phenytoin	Decreased levels of carbamazepine	Increase dose of carbamazepine as necessary
	Phenobarbitone		
	Theophylline		
Valproic acid	Antacids (aluminum- or magnesium-based)		
	Carbamazepine	Decreased levels of gabapentin	Do not administer antacids within 2 h of gabapentin
	Aspirin	Decreased level of valproic acid; enzyme induction	Increase dose of valproic acid as needed
Antidepressants SSRI (citalopram, fluvoxamine, fluoxetine, sertraline, paroxetine)	Rifampin	Increased free level of valproic acid—risk of valproic acid toxicity	Monitor valproic acid toxicity over time—if toxicity continues, consider decreasing dose
		Decreased clearance of valproic acid	Decrease dose of valproic acid while taking rifampin
	Monoamine oxidase inhibitors (MAO-I)	Increased toxicity of MAO-I (e.g., seizures, confusion, hyperpyrexia)	Avoid combination of SSRI and MAO-I
	Tricyclic antidepressant (TCA)		
	Diazepam	Increased toxicity of TCA	Avoid combination of SSRI and TCA
		Increased levels of diazepam	Avoid diazepam use if possible in the elderly; decrease dose if used with fluoxetine
		Increased effect of diazepam	Start with smallest dose of trazodone; decrease dose of trazodone if necessary
	Trazodone	Increased levels of trazodone	

(Continued)

Table 7 Drug–drug interactions of commonly used medications in the elderly (*Continued*)

Drug	Interacting drug	Mechanism/effect	Management
Sertraline Fluvoxamine	No clinically significant interactions		
	Astemizole	Increased levels of astemizole; increased risk of cardiac arrhythmia	Avoid use of astemizole with fluvoxamine; use alternate antihistamine
Paroxetine Citalopram	Benzodiazepines (triazolam, alprazolam)	Increased levels of benzodiazepine	Decrease dose of benzodiazepines
	Theophylline, caffeine	Increased levels of theophylline or caffeine	Decrease dose of theophylline by approximately 1/3; avoid caffeine intake
	Warfarin	Increased effect of warfarin; increased risk of bleeding	Monitor INR; decrease dose of warfarin if necessary
	Phenytoin Cimetidine	Decreased effect of phenytoin Increased levels of citalopram	Monitor phenytoin; increased dose may be necessary Monitor for side effects of citalo pram; reduce dose if necessary
Nefazodone	Azole (e.g., fluconazole, ketoconazole) and erythromycin	Increased levels of citalopram	Monitor for side effects of citalo pram during course of antibiotics
	Benzodiazepines (alprazolam, triazolam, midazolam)	Increased levels of benzodiazepines	Decrease dose (50–75%) of benzodiazepines
Bupropion	Levodopa	Increased effect from levodopa	Monitor for Levodopa toxicity; dose of Levodopa should be reduced if necessary
	Anticonvulsants	If anticonvulsant is used to control seizure disorder, bupropion may increase risk of seizures	Avoid use of bupropion in patients with history of seizure disorder
Venlafaxine Mirtazapine	MAO-I	Increased risk of toxicity	Avoid use of MAO-I while taking venlafaxine
	No clinically significant interactions		
TCA	Anticholinergic agents (e.g., antihistamines, low-potency neuroleptics)	Enhanced anticholinergic response	Avoid anticholinergic TCAs (use desipramine, nortriptyline when TCA is necessary); avoid combination with other anticholinergic agents
Cardiovascular			
Antihypertensives	NSAIDs	Decreased renal function, fluid retention; increased BP	Avoid use of NSAIDs if possible; use minimal dose when necessary
	Vasodilators (e.g., nitroglycerin)	Additive drop in BP; risk of orthostasis and falls	Lower BP to goal only; use nonpharm techniques to prevent falls
ACE-I	K ⁺ sparing diuretics; K ⁺ supplements	Increased K ⁺ retention; risk of cardiac arrhythmias	Monitor K ⁺ ; avoid K ⁺ -sparing diuretics while on ACE-I
Digoxin	Amiodarone	Increased level of digoxin	Lower dose of digoxin; smaller dose of amiodarone
	Diuretics	Hypokalemia, digoxin toxicity	Monitor K ⁺ ; supplement when necessary
Amiodarone	Warfarin	Increased levels of warfarin, potentiation of anticoagulant	Monitor INR; decrease warfarin dose
	Digoxin	Digoxin levels increased; increased risk of digoxin toxicity	Monitor digoxin levels, signs/symptoms of toxicity; decrease digoxin dosing

(Continued)

Table 7 Drug-drug interactions of commonly used medications in the elderly (*Continued*)

Drug	Interacting drug	Mechanism/effect	Management
Diuretics	Quinidine	Increased (free) levels of quinidine	Decrease dose of quinidine by 30–50%
	Procainamide	Increased levels of procainamide	Decrease dose of procainamide by 30% when starting amiodarone
	Phenytoin	Increased levels of phenytoin	Monitor phenytoin levels and s/s of toxicity; decrease phenytoin dosing if necessary
	NSAID/aspirin	Decreased fluid removal, minimized response of BP lowering effect	Avoid NSAID use if possible in the elderly
Warfarin	Lithium	Competition for lithium elimination; increased lithium levels	Avoid use of diuretics while using lithium; lower dose of lithium if necessary
	Amiodarone	Increased anticoagulant effect	Lower dose of warfarin (titrate to goal INR)
	NSAIDs/aspirin	Increased risk of bleeding	Minimize NSAID use while on warfarin
	Estrogen supplements	Pharmacodynamic interaction; procoagulant effect of estrogen	Increased dose of warfarin may be needed; estrogens contraindicated in patient with coagulation disorder
Endocrinology	Antibiotics (e.g., cotrimoxazole, ciprofloxacin, fluconazole, ketoconazole)	Increased levels, effect of warfarin	Monitor INR carefully during course of antibiotics; reduce dose of warfarin if necessary
	Calcium supplements	Decreased bioavailability of L-thyroxine	Take thyroid supplement on an empty stomach
	Sucralfate		
	Cholestyramine		
Sulfonylurea (e.g., glyburide, glipazide)	Colestipol	Alteration in L-thyroxine requirements (may ↑ or ↓)	Monitor thyroid function and adjust L-thyroxine as necessary
	Iron supplements	May block hypoglycemic responses	Use cardioselective β-blockers (e.g., metoprolol, atenolol); patient education to monitor for sweating
	Aluminum hydroxide	Enhanced hypoglycemic response	Monitor for signs/symptoms of hypoglycemia; manipulate diet or reduce dose of sulfonylurea
	Amiodarone		
Metformin	β-blockers		
	Fluconazole		
	High-dose salicylates		
	Sulfonamides		
Gastrointestinal	Contrast dye	Lactic acidosis and organ failure	Avoid use of contrast dye while on metformin; avoid renally toxic medications while on metformin
	Cimetidine	Decreased elimination, increased levels of metformin	Avoid use of cimetidine while taking metformin; consider using ranitidine or famotidine
	Carbamazepine		
	Diazepam	Inhibition of metabolism	Avoid use of cimetidine if possible; use ranitidine or famotidine
Cimetidine	Glipizide		
	Phenytoin		
	Theophylline		
	TCA		
Warfarin	Warfarin		

(Continued)

Table 7 Drug–drug interactions of commonly used medications in the elderly (*Continued*)

Drug	Interacting drug	Mechanism/effect	Management
Proton pump inhibitors	DigoxinIntraconazole	Decreased absorption of medications that are pH-dependent	Monitor response to medication; increase in dose may be necessary
	Iron salts		
Metoclopramide	Ketoconazole	Antagonism of dopamine by metoclopramide	Avoid use of metoclopramide in patients with Parkinson’s disease
	Dopamine replacement		
	Parkinson’s disease medications	Medications that slow GI motility antagonize the effect of metoclopramide	Avoid use of antagonistic medications
	Anticholinergics		
Narcotics			
Neuroleptics			
Neuroleptics	Antiparkinson’s medications	Neuroleptics may exacerbate or cause Parkinsonian movements	Avoid use of neuroleptics (except clozapine) in Parkinson’s patients
	Antihypertensives	Increased risk of orthostasis, hypotension	Monitor BP in patients; reduce dosage of medications as necessary to prevent falls, dizziness
Haloperidol			
	Carbamazepine	Increase metabolism, decreased effectiveness of haloperidol	Increase haloperidol dose as necessary
Respiratory			
Theophylline	Phenytoin	Decrease serum levels of theophylline	Increase theophylline dosing as needed
	Rifampin		
	Carbamazepine		
	Allopurinol	Increase serum levels of theophylline	Decrease theophylline dosing to prevent toxicity
	Cimetidine		
	Ciprofloxacin		
Corticosteroids	Erythromycin	Increased hyperglycemia from steroids; loss of control of blood glucose levels	Monitor serum glucose closely; increase hypoglycemic medications or add insulin as necessary
	Antidiabetic medications	Increased GI intolerance; risk of GI bleeding	Avoid use of concomitant therapy if possible
	NSAIDs	Increased risk of hypokalemia	Monitor K ⁺ and replace as necessary
	Amphotericin B loop diuretics		

ACE-I, indicates angiotensin converting-enzyme inhibitor; BP, blood pressure; CNS, central nervous system; GI, gastrointestinal; INR, international normalization ratio; K⁺, potassium; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin receptor inhibitor; TCA, tricyclic antidepressant.

Table 8 Clinically significant drug and food interactions in the elderly

Class of drug	Interaction	Clinical significance	Recommendation
Anti-infectives			
Antibacterials			
Azithromycin	Food decreases absorption	May lower concentration of antibiotic by >50%	Space medication and food at least 2 h apart
Erythromycin	Food decreases absorption; food may decrease some GI upset	Most patients have GI complaints and may prefer to take erythromycin with food; however, this may lead to decreased absorption	Space medication and food 2 h apart if patient can tolerate; if GI complaints, take erythromycin with small snack
Fluoroquinolones (e.g., ciprofloxacin)	Dairy products, iron, multivalent cations decrease absorption of fluoroquinolones	Quinolones ineffective because of chelation	Administer medication at least 2 h apart from any foods
Metronidazole	Alcohol-containing products may cause a disulfiram-like reaction	Nausea, vomiting, vasodilation may be experienced by patients	Avoid all alcohol-containing products while taking metronidazole
Penicillins (oral)	Food decreases absorption	May lower concentration of antibiotic	Space medication and food at least 2 h apart
Tetracyclines	Dairy products, iron, multivalent cations decrease absorption of tetracycline	Tetracycline ineffective because of chelation	Administer medication at least 2 h apart from any foods containing cations
Antifungals			
Griseofulvin	High-fat meal increases absorption	If medication given without a fatty meal, griseofulvin ineffective	Administer with fatty foods
Ketoconazole	Possible insulin-sparing effect	Patient may experience lower blood glucose concentrations on the same insulin dose	Monitor for decreased insulin requirements
	Interference with vitamin D and steroid metabolism	Osteomalacia may develop if long-term administration of ketoconazole is used	Ensure adequate vitamin D and calcium intake Monitor calcium and phosphorus levels if ketoconazole is used long-term
Antituberculars			
Isoniazid	May decrease pyridoxine (vitamin B6); food may decrease absorption of isoniazid	Peripheral neuropathy may develop; decreased absorption of isoniazid may lead to therapeutic failure	Supplement individuals with vitamin B6 50 mg daily; administer isoniazid at least 2 h apart from any foods
Rifampin	May decrease effect of vitamin D	Individuals may be predisposed to osteomalacia	Ensure adequate vitamin D and calcium intake during long-term therapy

(Continued)

Table 8 Clinically significant drug and food interactions in the elderly (*Continued*)

Class of drug	Interaction	Clinical significance	Recommendation
Anticoagulants Warfarin	Vitamin K—green leafy vegetables and green tea antagonize warfarin	Large amounts vitamin K can decrease INR leading to therapeutic failure of warfarin	Avoid excessive consumption of green leafy vegetables; do not alter diet once anticoagulation with warfarin is stabilized
Anticonvulsants Phenytoin	Reduced levels of vitamin D due to increased metabolism of active vitamin D metabolites Administering medication with enteral feeds binds phenytoin Decrease in folate concentrations	Osteomalacia and rickets have been reported with long-term anticonvulsant therapy; additional risk factors for these conditions (e.g., poor sunlight exposure) increases risk Enteral feeds can significantly lower absorption of phenytoin Long-term therapy may put patients at risk of folate deficiency	Ensure adequate supplementation of vitamin D, 400 IU daily Hold enteral feeds for minimum of 1 h while administering phenytoin Close monitoring of gingival hyperplasia and megaloblastic anemia if patient is using long-term phenytoin therapy; consider supplementing folate starting at 1 mg daily for prevention
Antidepressants MAO-I (e.g., isocarboxazid, phenelzine, tranylcypromine) Tricyclic antidepressants (e.g., amitriptyline, desipramine, nortriptyline, etc.)	Tyramine-containing foods lead to excessive sympathetic stimulation Medications inhibit breakdown of food because of decreased saliva production; food in general may cause xerostomia	Hypertensive crisis can develop May cause difficulty in swallowing food	Avoid aged, fermented, pickled, or smoked foods Suck on sugarless hard candy, ice chips, or chew sugarless gum
Antihistamines Chlorpheniramine, dimenhydrinate, diphenhydramine, etc.	Medications inhibit breakdown of food because of decreased saliva production; food in general may cause	May cause difficulty in swallowing food	Suck on sugarless hard candy, ice chips, or chew sugarless gum
Autonomic medications Ephedrine, pseudoephedrine, amphetamines	Caffeine may cause increased nervousness and insomnia	Most significant if taken before bedtime	Minimize daily caffeine intake while using stimulating medications

(Continued)

Table 8 Clinically significant drug and food interactions in the elderly (Continued)

Class of drug	Interaction	Clinical significance	Recommendation
Cardiovascular medications ACE-I (e.g., lisinopril, enalapril, ramipril, etc.) Captopril	Salt substitutes containing potassium	Potassium-containing substitutes and an ACE-I can result in hyperkalemia	Avoid potassium-containing salt substitutes
	Food decreases absorption of captopril	Taking with food may minimize blood pressure-lowering effects	Space medication and food 2 h apart or take at the same time every day
	Zinc deficiency with high-dose, long-term use	Most pronounced in individuals receiving at least 150 mg daily; taste impairment a marker of zinc deficiency	Monitor for taste impairment; zinc supplementation has not been definitively shown to be of benefit
	High-fiber, high-pectin foods delay and decrease absorption	May minimize the benefit of digoxin	Avoid administering digoxin with high-fiber foods; administer at the same time every day
Potassium-sparing diuretics (e.g., triamterene)	Potassium-containing salt substitutes may lead to additive effect of increased potassium	Excessive amounts of potassium may lead to cardiac arrhythmias	Avoid potassium-containing salt substitutes
Corticosteroids Hydrocortisone, prednisone, methylprednisolone	Decreased glucose tolerance with carbohydrates	Rapid, small elevation in blood glucose can be seen. Glucose levels do not normalize until steroid therapy is discontinued	Monitor blood glucose levels in persons with diabetes
	Triglycerides and cholesterol may increase	Long-term use may accelerate atherosclerotic processes	Monitor patients at risk of heart disease or elevated cholesterol/triglyceride levels on long-term steroid therapy
	Possible insulin sparing effect with ketoconazole	Patient may experience lower blood glucose concentrations on the same insulin dose	Monitor for decreased insulin requirements
Diabetes medications Insulin	Interaction with the absorption of vitamin B12	Patient may experience vitamin B12 deficiency	Monitor levels closely in patients predisposed to vitamin B12 deficiency
Metformin			
Gastrointestinal medications Misoprostol	Increases GI motility, nausea, distress if taken on empty stomach	Taken without food can dramatically increase GI side effects	Take with food

(Continued)

Table 8 Clinically significant drug and food interactions in the elderly (*Continued*)

Class of drug	Interaction	Clinical significance	Recommendation
Sucralfate	Food (protein) decreases binding of sucralfate to gastric mucosa	Ineffective binding leads to lack of protection for gastric ulcers	Give sucralfate at least 1 h before meals to allow adequate binding to the gastric mucosa
Lipid lowering medications			
Cholestyramine	Binds iron, folic acid, essential fatty acids, vitamin A	Cholestyramine can significantly lower absorption of nutrients	Consider vitamin supplementation and monitor iron status for long-term use of cholestyramine
	Calcium absorption may be impaired	Long-term use of cholestyramine may increase risk of osteoporosis	Ensure adequate calcium, vitamin D intake by spacing supplements at least 2 h from administration of cholestyramine
Lovastatin	Improved absorption if given with food	If taken on an empty stomach lipid-lowering effect may be minimized	Take with evening meal or snack to maximize absorption of lovastatin
Pulmonary medications			
Theophylline time-release	High-fat meals—rate of absorption can be affected	Elevated theophylline levels may result, possibly causing tachycardia, palpitations, irritability, and tremor	Avoid administering medication with high-fat foods, altering diet while on the medication, or take 1 h before eating
Pain medications			
NSAID (e.g., ibuprofen, naproxen, piroxicam)	Gastric irritation may occur from direct GI contact or through systemic mechanisms (i.e., irritation may occur with suppositories or enteric coated products)	Severe gastric irritation may occur if taken on an empty stomach	Take with food to minimize gastric irritation
Parkinson's medications			
Anticholinergic medications (e.g., benztropine, procyclidine)	Medications inhibit breakdown of food because of decreased saliva production; food in general may cause xerostomia	May cause difficulty in swallowing food	Suck on sugarless hard candy, ice chips, or chew sugarless gum
Levodopa	Competition for absorption with protein	Minimize or nullify benefit of levodopa	Space medication and food 2 h apart or administer with nonprotein meal
Psychiatric medications			
Lithium	Sodium and lithium compete for reabsorption/elimination	Altering sodium intake may alter lithium level	Do not change diet once lithium is stabilized

the amount believed necessary. Causes of intentional or unintentional nonadherence include medication regimens that are difficult to fit into the patient's lifestyle, unwanted effects, expensive medications, or patient's inability to self-administer the product (33, 34). Most important, if patients do not believe they need the medication, they will be less likely to take the prescription.

Risks for nonadherence have been studied, and some of the findings include the complexity of dosing schedule (e.g., four times daily versus once daily dosing); frequent changes in medication; substitution of medication (therapeutic or generic); multiple medications; unpleasant side effects; difficulty in opening containers; cost; difficult routes of administration; inadequate patient education/understanding; and cognitive, visual, or physical function impairment (31, 33, 34). Patients who already have vision or mobility problems may become noncompliant when some of the factors noted above are added to their existing challenges with medication management.

Factors that have been linked to improving adherence include a belief that the medication is important, a belief that it is effective, and regularly attending the same medical clinic and pharmacy (34).

A number of studies have also tried to determine indicators of poor self-medication management. Some of these indicators are cognitive impairment (MMSE <24), physical dependency (Katz \geq 1), and poor self-reported medication management (35).

When prescribing medications for the elderly, it is important to consider physical disability, visual impairment, the shape or color of medications (ability to differentiate), and the belief system of the patient (35, 36). It would be beneficial to have healthcare professionals review the technique of using certain devices and to discuss the use of compliance aids.

Various compliance aids have been studied in an attempt to increase adherence to prescribed regimens (36–38). These aids include alarm clock devices, blister packing, calendar packaging, and more. Some providers feel they greatly assist patients who otherwise would become confused or could not manage multiple medications on their own, which would increase their risk of an adverse event or nonadherence. It has also been argued that these aids can be difficult to use, and the patients who benefit most are often those who would likely manage well without any aids. There are studies providing support for both views, and the subject requires additional study.

It is important to consider that even with compliance aids, the patients must receive appropriate counseling and instruction on how to manage the devices properly (37, 38). The aids must also be recommended and agreed to by the patient for them to be of use. For example, if a patient feels

they have lost some of their independence by having to use blister packaging, they are still not likely to become compliant. However, if the patient has agreed that an aid would be helpful and save them time, they are more likely to appreciate the additional assistance and will use the product to increase adherence. Patient preference, agreement, and education are still the most important factors in improving adherence. Additional factors that must be considered are the medication effects. If a patient discontinues a prescription because of side effects, packaging the medications into a compliance aid will not improve adherence. Before a compliance aid is considered, the reason for nonadherence must be carefully reviewed (39) because an aid may not be necessary at all and may offend patients if they think the provider feels they are becoming cognitively impaired.

Polypharmacy

When translated, polypharmacy simply means multiple medications. However, the clinical interpretation of this term usually refers to the use of multiple medications in an inappropriate, illogical, or harmful manner to the patient.

It is expected that the elderly have a higher incidence of chronic disease and will be prescribed more medications to manage their diseases. It is very easy to quickly reach a state of polypharmacy. Risk factors include multiple doctors, diseases, and pharmacies (40). Patients often present with a variety of complaints but may lack a diagnosis, triggering the prescription of medications that are used to manage the complaints that do not resolve the illness. Patients also use numerous nonprescription medications, which may go unmonitored and yet have the potential to interact with prescribed medicines. Patients seeing multiple doctors is often a concern because specialists may not take into consideration other prescribed medications before ordering new drugs for the patient. Similarly, some physicians may not be aware that their patients are seeing other doctors, causing difficulty in monitoring prescriptions in these of patients.

Although it is somewhat controversial, certain personality traits in elderly patients may predispose them to using more medications (36, 40). Elderly patients and their physicians may also be reluctant to discontinue medications. Often, patients with these views feel it is necessary to use medications and to obtain more prescriptions each time they visit a physician. This may also tie in with the attitudes of healthcare providers, who may be pressured to prescribe more medications for the patient. Finally, polypharmacy may be common in the elderly because they often borrow medication from family or friends, sometimes because of lack of education about the risks of inappropriate medication use.

Tablet Splitting

Tablet splitting is common in the elderly population (41) often because of cost-savings and the production of larger dosage strengths to meet the needs of younger patients. The prescriber may feel that the patient requires much less medication than a typical dose and consequently prescribes a dose that the patient must split. This is done frequently with medications that are adjusted throughout the course of treatment, such as warfarin for anti-coagulation. Tablet splitting is also common when titrating medications that cannot be started in full doses because of intolerance. A common example of this is the use of β -blockers post-MI when only small doses are tolerated at the onset, but when the goal is to reach a much higher dose.

This topic has been studied only in a small number of studies and often focuses on younger subjects (42). The process of tablet splitting is also not generalizable to the elderly population because the muscle strength, fatigue, and duration of time to split are often measured in young patients doing repetitive tablet-splitting tasks, which does not reflect the typical scenario in an elderly patient's home.

Underutilization/Undertreatment

Both undertreatment and underutilization of medications are common problems in the elderly. It is often a result of stereotyping by healthcare professionals, lack of education of managing medications in the elderly, and lack of research (4). Examples include treatment of hypertension, prescribing hormone therapy, osteoporosis, treating MI, lipid management, pain management, and depression.

DETERMINING MEDICATION APPROPRIATENESS IN THE ELDERLY

There have been many attempts to characterize and quantify the "appropriateness" of medications in the elderly. The first such scale was developed by Hanlon and is called the Medication Appropriateness Index (43). It has been used most frequently in the Veterans Affairs population in the United States.

Beers et al. (44) developed a list of medications that were considered inappropriate in a nursing home population. Their most recent list further describes appropriate doses of medications that should be used in the elderly (44). For example, digoxin is suggested to be given at 0.125 mg daily because most elderly patients either

become toxic or do not require higher doses for efficacy. Other lists have been developed (11) and updated (10). These lists are generally considered guidelines and should be used with professional judgment when prescribing and managing dosing in the elderly. Other tools have also been studied and are being developed. A review of different instruments has been written by Shelton et al. (45).

DOSAGE FORMS

Geriatric patients are able to use any type of dosage form available; none are contraindicated based on age alone. The most frequently used dosage form in the elderly is the oral route; however, other dosage forms may be used based on disease state. For example, chronic obstructive pulmonary disease is common in the elderly, and the route of choice for administration of medications is by inhalation. Therefore, this population frequently uses inhalers. Another common dosage form used in geriatric patients is eyedrops. Dosage forms requiring hand strength or coordination may be difficult to administer in some geriatric patients with certain conditions such as arthritis, weakness after a stroke, dementia, or other impairments. The challenges with each of these dosage forms are presented later.

Inhalers

Lung diseases such as COPD and asthma are common in the elderly population. The cornerstone of treatment of these conditions is to use medications administered by inhaler, using either a turbuhaler, nebulizer, metered-dose inhaler (MDI), diskhaler, or other breath-activated device. These devices often require good eyesight, hand-eye coordination, hand strength to depress the MDI, and intact cognition to manage the device. Age itself has been found to be a predictor of poor technique; however, other studies (46) found that other disease states that increase with age are more significant predictors of success in using MDIs. A patient with poor hand strength, such as a patient with rheumatoid or osteoarthritis, may have difficulty managing the inhalers. Patients who are blind or have decreased vision may also have difficulty organizing their inhalers in the proper order or manipulating any of the devices. Cognitive decline is also more common in elderly patients and tends to increase with age. This has been found to be a determinant of poor technique when using inhalers (46). It is important for healthcare professionals to assess the ability of patients to use inhalation devices before they are prescribed. Repeated counseling and education are

necessary to maintain good technique and appropriate use of these devices in the elderly population (38, 46, 47).

Eye Drops

Disease states frequently requiring medication such as eye drops are common in the elderly. Many elderly patients also use nonprescription natural tear replacement products for lubrication. It is therefore common to have elderly patients using eye drops, even though there are many challenges and difficulties in administering medication by this route. The majority of patients, when asked, admit to having difficulty administering eye drops (48). There is difficulty in raising arms above one's head, which can result from limited range of motion secondary to arthritis or deconditioning. It is also necessary to be in the supine position or to tilt one's head far back to keep the drops in the eye. This is often difficult for patients because of neck osteoarthritis or stiffness. It is also very challenging to aim the drops accurately. A number of devices have been studied, but none make compression of the drops easier (48). It is often difficult for patients to compress the bottle to release the drops, and some patients do not use correct technique and expel more than the required amount of drops. Some of the reasons for difficulty in administering drops are similar to those listed above for difficulty with actuating MDIs. Most of the devices appear to help improve aim only, which is just one part of the problem for elderly patients. Difficulty with eye drops commonly results in treatment failure as patients become nonadherent or administer drops incorrectly and receive less benefit than could be expected. It is important to review technique and to prescribe appropriate compliance aids to make administration easier for patients because often, there are no other options but to use eye drops for ophthalmic conditions.

CONCLUSION

Considering the diversity and challenges in dealing with the geriatric population, it is important to be aware of the physiological changes that occur with aging and the complications that can arise when these changes are not considered when dosing medications. It is also important to be aware of the potential problems that can arise in treating geriatric patients with multiple disease states because they are more likely to experience adverse events and to have more drug-related problems such as nonadherence. Although each patient should be managed individually, there are important principles that should be considered when working with geriatric patients to optimize the dosing and dosage forms used in this population.

Genetic Aspects of Drug Development

Werner Kalow

University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

The science of genetics is currently changing in a way that we cannot neglect when looking at drug development: Traditional genetics was solely concerned with structural variation of genes. New techniques led to the recognition that the expression of genes can vary.

Traditional medicine was not much concerned with genetics, except for genetic diseases. However, genetic diseases are always rare because disease-causing gene alterations render them evolutionary disadvantageous; hence such alterations tend to be eliminated by Darwinian selection. However, it is now realized that most or all common diseases are contributed to by genetic factors. It is thus predictable that genetic considerations will become increasingly important in medicine.

Most drugs on the market nowadays were developed without much concern for genetics, or perhaps with restricted concerns, although genetic factors are well known to be able to alter an individual's response to a drug; a person may show a lack of response or an over-response that in some cases has been fatal. Such gross differences are hoped to be eliminated in the future or at least curtailed because the new genomic techniques may increase the knowledge of genes that can affect both drug safety and efficacy. The present choice of a drug for treating any disorder is not based on causes but on diagnostics and statistics. This is hoped to be changed to become "personalized medicine," which means choosing the right drug for a given patient on the basis of that patient's genetic makeup. While many genes can contribute to all common diseases, but only one or a few are likely to be the main contributors to the disease in that patient. In other words, the hope is to choose a drug for treatment that affects the impact of the particular gene, which causes or enhances the disease in that person. The common diseases contributed to by multiple genes include cardiovascular, asthmatic, and schizophrenic disorders, among many others. The rise of genomic techniques will convert single-gene pharmacogenetics into multiple-gene pharmacogenomics.

In order to realize the hope, a number of tasks will have to be performed. A primary task will be the identi-

cation of the genes whose malfunction contributes to, or can cause, the disease to be treated. Once the gene of interest is identified by genomic methods, it will be necessary to define its function; this will usually require knowledge of the protein produced by the gene via translation. By establishing the normal gene function, recognition of the malfunction is facilitated and its contribution to the disease may become clear. It then becomes possible to look for chemicals that can attach to the gene or to the protein, thereby eliminating or relieving the faulty gene function. Finally, the chemical may be converted to a drug.

All these processes require scientific views. The purpose of this article is to provide an overview at the scientific backgrounds for this study and for the required procedures.

BACKGROUND DATA

Variability of Gene Function

Genes determine the appearance, actions, and much of the fate of any individual, be it a bacterium, a plant, or a mammal. Our genes make any human different from anyone else. This means that the genes cannot be similar in different individuals. In fact, most subject-to-subject differences depend, and evolution depended, on variability of genes, that is, on gene mutations.

Most mutations represent the replacement of one base by another; a minority is caused by deletions of some base pairs, by frameshift, by polypeptide chain elongation due to mutation of a terminator codon, or by recombinational events with mutation-like effects. The replacement of one base for another is currently indicated by the term "single-nucleotide polymorphism," abbreviated as "SNP."^[1,2] It occurs at a frequency of roughly one per every 500–1000 base pairs of genomic DNA, which means that most genes carry one or two SNPs, although many are without any functional significance.^[3]

Techniques developed in recent years have opened a totally new aspect of genetics, that is, the study of gene expression.^[4–6] That is, the DNA of a given gene may lead to the production of varying numbers of its derivative RNA, the protein-forming nucleic acid. As a consequence,

the function of a gene may vary, independent of gene structure.

Gene expression is controlled by transcription.^[7] Transcription is the formation of one-stranded RNA from DNA, the gene consisting of a two-stranded nucleotide coil. The process involves unwinding of DNA. It is catalyzed by RNA polymerases, enzymes controlled by complicated factors.^[8] Posttranscriptional processing of the messenger RNA (mRNA) involves the removal of introns by splicing. The formation of protein from RNA by translation is again a complex process.^[9] Translation can be inhibited by antisense oligonucleotides.^[10,11] Thus, gene expression involves complex processes. It can be affected by hormones, diseases, and (importantly) by drugs.

Furthermore, gene expression can be controlled by epigenetics, a potentially reversible change in DNA methylation.^[12,13] Its normal functions are regulation of gene activity during aging, tissue-specific DNA modification, and X-chromosome inactivation. Epigenetics may contribute to cancer control.^[14] In short, a look at gene structure and mutations may no longer be good enough to alone serve the hunter for personalized medicine.

Interactions of Genes and Drugs

Pharmacogenetics started with the discovery of variable responses of different people to a given drug, as summarized in papers by Motulsky^[15] and Vogel,^[16] and in the book by Kalow.^[17] Before genes could be tested, allelic variations were phenotypically indicated as a cause by the occurrence of abnormal drug responses within families or groups of twins. Also, response abnormalities in different human populations were known early, at first only assuming a genetic cause of such population differences.

All these early reports of inborn differences dealt with distinct abnormalities in drug response that were monogenic (Mendelian) in character. It is a different matter when we observe that only a few people respond exactly alike to a given drug. This observation was mathematically formalized by the introduction of the concept of "ED50," meaning the dose of a drug that had the desired effect in 50% of population.^[18] The utility of the ED50 indicates that an unequal response of individual animals or humans to any drug is a rule and is often very large. This variability can be graphically represented by a normal (Gaussian) distribution curve with ED50 as the mean. The first evidence that genetic factors can also be involved came from systematic studies of twins, which indicated genetic control of various drug metabolizing capacities.^[19]

Thus, the genetics of a drug response can be of two kinds, which deserve a clear distinction: First, the particular genetic variant of a particular gene may strongly affect the

response to one drug, or to a series of drugs. Second, there can be multifactorial variation of a drug response caused by effects or influences of many genes, usually more or less modified by environmental factors. The examples of these two kinds of variation in order to clarify their impact are given below.

The first case is well illustrated by the studies of CYP2D6, a drug-metabolizing P450 cytochrome that is prominent in human liver. This protein contributes to the metabolism of about 60 different drugs.^[20] So far, 74 alleles have been found in that gene, most often several mutations (up to 8) per allele. The difference in the consequences of CYP2D6 mutations deserves attention: A few of the mutations prohibit the formation of CYP2D6, others totally eliminate its biological activity, some of them merely decrease its activity,^[21] others change its activity toward selected drug substrates,^[22,23] and gene duplication may cause greatly increased activity in some subjects.^[24]

The absence of CYP2D6 activity occurs in about 7% of Caucasians, in less than 1% of Asians and most Africans,^[25] although it is absent in about 20% of San Bushmen.^[26] A mutation identified in about 50% of Chinese subjects causes a substantially decreased average CYP2D6 activity in China compared to Europe.^[27] Of seven precisely investigated CYP2D6 mutations, a few were found in Europe, others in China and Africa, but only one (G4268C) was found everywhere (in Europe, China, Japan, and Africa), suggesting that this is an old mutation that occurred prior to the migration of *Homo sapiens* from Africa.^[25] Thus, differences in the timing of mutational events may account for most interethnic differences of drug-metabolizing enzymes because such mutations tend to be biologically irrelevant in the absence of drugs.

These data show that there can be great complexity even if we deal with a single variable gene as in traditional pharmacogenetics. It is a relatively simple process to count the absence of enzyme activity ("the poor metabolizer phenotype") in one population, but data thus obtained, for instance, in Europe, may be useless everywhere else.

Multifactorial control of drug responses cannot be described in similarly clear terms, but some examples can be given. For instance, one may look at the two groups of homozygous subjects with respect to debrisoquine's metabolism, i.e., there are those homozygous for the wild-type CYP2D6 and those without the enzyme. In each group, there is a large interindividual variability of debrisoquine's persistence. This can be accounted for only by the presence and variability of numerous factors other than the CYP2D6 genotypes contributing to the drug's elimination.^[25] Multifactorial control is present whenever response curves show a Gaussian distribution. Vesell^[28]

cited examples to show that the metabolism of various drugs was mainly under genetic control, even when the metabolism was not due to an identifiable single gene. Table 1 indicates the potential complexity of drug metabolizing control even if there is only one identified catalyst.

Because of old and available methodologies, drug metabolism and other forms of drug elimination are particularly well-investigated fields. However, the variability of drug effects can also depend very much on genetic variation of drug targets, such as drug receptors.^[29] Kim and Wilkinson^[30] described the variation of drug transporters and the effects.

Drugs can also influence gene expression. A good recent example is the determination of changes produced by rifampin. Rae et al.^[31] used microassays to measure the effects of that drug on the overall pattern of mRNA expression of drug-metabolizing enzymes in human hepatocytes. There was no effect on CYP2E1 or CYP2D6. The drug caused a 6.5-fold increase in the expression of CYP2C8 and a 3.7-fold increase of CYP2C9, but had no effect on CYP2C18 mRNA. CYP3A4 showed the highest level of 55.1-fold induction.

It is now recognized that drugs can affect the activity of many genes by enhancing or inhibiting their expression. In fact, we often might be unsure whether a drug effect represents an interaction with a protein or with its gene. For instance, it seems that the addictive effect of nicotine or other drugs results from altered gene expression produced by these drugs.^[32]

It has to be mentioned that nongenetic or environmental influences may also have great impact. Starvation, malnutrition, and protein deficiency can all cause a decreased rate of drug disposition,^[33] but so can even

relatively minor food deficiencies.^[34] Some foods or drugs cause enzyme induction^[35] and others cause enzyme inhibition.^[36] Infections, other diseases, and many factors that can affect hormonal functions may alter a drug response. It is well established that cigarette smoking causes induction of some drug-metabolizing enzymes. However, the extent of smoking varies between individuals and between populations, in part because of genetic variability of the nicotine-metabolizing cytochrome CYP2A6;^[37] this is an example showing that genetic predisposition can affect the magnitude of an environmental impact.^[38] Many drug responses are influenced by gender and age; both factors are controlled by genes but also by time.

Regardless of all these complexities, the fact that drug action always depends more or less on genes is important, although the control may be exercised by one or by a multiplicity of genes.

Genes and Diseases

The term "genetic diseases" refers to diseases that are essentially caused by faulty function of a single gene. Although they are Mendelian disorders, their phenotypic expression can vary from case to case.^[39,40] Examples are, for instance, cystic fibrosis, neurofibromatosis, Marfan syndrome, and Huntington disease. All these diseases are rare because the producing genetic variants are disadvantageous from an evolutionary point of view. Because of the rarity, there are few broad-based efforts to find drugs for their treatment. These limitations also express societal and economic concerns.

All common diseases are caused, or contributed to, by many genes, often interacting with environmental factors.^[41] Examples are, for instance, arthritis, atherosclerosis, asthma, schizophrenia, and Alzheimer's disease. Many cases are cited in the book *The Genetic Basis of Common Diseases*.^[42] Loring et al.^[43] found 118 differently expressed genes in Alzheimer brains. Gharavi and Lifton^[44] describe the hereditary basis of blood pressure variation and hypertension: Identified to date are mutations in seven genes that raise blood pressure and in nine genes that lower blood pressure in humans. Many of these genes control renal salt handling. Some cases suggest the presence of angiotensinogen variation, or changes in beta-adrenergic or dopamine receptor system. There are also Mendelian (monogenically controlled) cases of human hypertension, indicating that the disease is not necessarily controlled by many genes. As indicated in the four-volume book by Scriver et al.,^[45] many diseases show similar complications.

It is a principal difficulty that medical diagnosis is currently almost always dictated by the appearance of any

Table 1 Factors that may cause reduced metabolism of a drug

1. Alterations of the enzyme's gene
 - Structural variation of the gene through mutation
 - Reduced expression of the gene (caused by gene–gene interaction, effects on the gene by drugs, hormones, or foods), by epigenetics, or by unstable RNA
 - Reduced function: failing transcription or translation (protein formation)
2. Alterations of protein concentration or function
 - Enzyme destruction or instability reduces its concentration
 - Enzyme inhibition by drugs, hormones, foods, and infections
 - Mistaken protein folding
3. Reduced access of drug to enzyme
 - Excessive drug binding (e.g., in tissues or to albumin)
 - Genetic variation of a transporter protein

A Question: Which of these factors cause the typical age-related reduction of enzyme activity?

disease, perhaps by a single prominent symptom, but usually does not reveal the cause of the disease. This is a shortcoming that is hoped to be overcome by defining the genes which are altered in a case of common disease. However, knowing the crucial genes will allow the investigation of their function, and knowing the function may reveal the contribution of the gene's failure or its action to the disease. The final question is which gene contributes to the disease of which patient.

Disease Genetics Determines Drug Action

Multiple treatments are available for most of the common diseases, but they often fail, and a given patient may benefit from only one or the other of the recommended drugs. In some cases, genetic factors affecting the disease are known to determine whether a drug is beneficial or useless for that patient. Let us consider a few examples given below.

Data on asthma are a good example of the complexities of interacting genes, diseases, and drugs. First, there is no universally accepted definition of asthma. Twin studies suggest that asthma is to 0.72%–0.8% a genetic disease,^[46] but inheritance does not follow a clear Mendelian pattern, and environmental factors modulate the clinical expression.^[47] Thus, asthma is multifactorial. Disease expression is influenced by interactions between multiple major and minor genes, and modulated by environmental factors.^[48]

Drazen et al.^[49] emphasize the heterogeneity of therapeutic responses in asthma. Current asthma therapy employs several different drugs aimed at different targets. Inhaled glucocorticoids like beclomethazone are used as anti-inflammatory drugs, acting on glucocorticoid receptor alpha.^[50] β_2 -Adrenoceptor agonists like salbutamol protect against histamine-induced bronchoconstriction.^[51] Cysteinyl-leukotriene inhibitors, i.e., ACE-inhibitors like fosinopril, counteract slow-reacting substances of anaphylaxis.^[52] Among additional factors, driving and maintaining the asthmatic inflammatory process appear to be an abnormal or inadequately regulated CD4+ T-cell immune response.^[53] The variable platelet-activating factor (PAF) acetylhydrolase and oxidized derivatives of phosphatidylcholines play important roles as causative factors in asthma and other diseases.^[54] The gene NOS1 regulating neuronal nitric oxide is associated with allergic asthma, as shown in studies of mice and humans.^[55]

Other broad-based examples besides that of asthma could surely be found. However, there are other established though more restricted examples. Well known is the failure of treatment of Alzheimer's disease by tacrin if the patient has a variant of ApoE4, an apolipoprotein. Tacrin

is a cholinesterase inhibitor, one of the first anti-Alzheimer drugs,^[56] chosen to elevate the brain levels of the transmitter acetylcholine, a transmitter that was low because of deficient formation by the enzyme choline acetyltransferase.^[57] The contribution of a genetic variant of ApoE4 to Alzheimer's disease was an independent later observation.^[58] Then, the discoverer of this contribution noticed that patients with the ApoE4 variant tended to respond poorly to tacrin.^[59]

Another example is the genetic variability of the effects of neuroleptic drugs in schizophrenia. Cichon et al.^[60] have shown that this variable responsiveness can be caused by genetic variation of several of the P450 cytochromes, plus variation of dopamine and serotonin receptors. Because variation of these receptors seems to contribute to the schizophrenic disease, this is another example of interaction of genetic effects, diseases, and drug response.^[61–63]

All these observations support confidence in research aimed at the development of personalized medicine, that is, at the development of treatments that affect the function of genes which contribute most to a patient's disease.

THE TASKS

Searching for Genes of Interest

Foremost will be the search for mutations that are responsible for, or substantially contribute to, the occurrence of the common disease of interest. Association studies^[64] will provide the link between the disease and a genetic variant. Of the millions of DNA sequence variants in the human genome, the majority is single-nucleotide polymorphism (SNP). Determination of SNP-based genetic profiles may be viewed as individual fingerprints, indicating relative genetic contribution of the risk for various illnesses. This is the driving force behind intense efforts to establish the technology for large-scale analysis of SNPs.

Many technological descriptions of gene searching were published recently. For instance, Kwok^[65] summarized a number of genotyping methods currently in use. All effective designs require genotyping of a large number of individuals with a large number of markers. Therefore, the whole genome must be searched for the chance to find responsible genes. There is multiplex genotyping^[66] and minisequencing.^[67] Medlin^[68] used "inkjet technology" to propel DNA nucleotides onto slides. Qi et al.^[69] described a flexible, non-gel-based detection method, using thermostable ligation for allele ligation and rolling circle amplification (RCA) for signal enhancement. Tsongalis et al.^[70] described a system utilizing DNA polymerase-

mediated pyrophosphorolysis and a luciferase detection reaction. Patil et al.^[71] set out to identify all SNPs in human chromosome 21 and to group them into blocks of haplotypes. They established human–rodent hybrid cell lines, each containing one copy of human chromosome 21 from a different individual. Using high-density oligonucleotide arrays, they obtained complete DNA sequences in that human chromosome. Further methods will be developed and described. Nevertheless, the search for genes underlying complex traits has been difficult and often disappointing.^[72] The main reason for these difficulties is that several genes, each with rather small effect, might be interacting to produce the trait.

Probably just as important as the search for structural variants of genes will be the exploration of gene expression data. Gene expression can be compared between cells derived from particular tissues, or obtained from the same tissue at different times. If the tissue was disease free on first but not on second sampling, and if the expression of some genes were found to differ between the samples, one would know which genes are altered by the disease, or which may be its cause. By the same method, one could learn which genes are affected by a drug or toxin, or which change with age, or which are expressed in one but not in another tissue. One would know the gene with which to deal, and one would start to understand the biological role of a gene. It could mean identification and validation of new molecular targets for drug development, and prediction of potential side effects during preclinical development and toxicology studies.^[73,74]

Gene expression studies require microarray technology. Recently, high throughput technologies for biochemical analysis of gene expression have come into use.^[75–78] Serial analysis of gene expression (SAGE) is a widely used method.^[6] Burgess^[79] spotted different probes on a glass microscope slide and labeled the RNA isolated from the cells with two different fluorochromes before being hybridized to the microarray. Gene expression as whole profiles can replace the conventional focus on an individual gene.^[80]

Conceptually different approaches to the development of this technology resulted in the generation of two different array formats: oligonucleotide arrays and cDNA arrays.^[81] Oligonucleotide probes represent mispaired bases in DNA segments. Lee et al.^[82] stressed the importance of studying replications to insure data reliability, while Herwig et al.^[83] presented a statistical evaluation of expression data. Brazma et al.^[84] proposed a standard for presenting and exchanging such data in form of “minimum information about a microarray experiment” (MIAME). Haverty et al.^[85] established the “human gene expression index” (www.HugeIndex.org) to serve as a public

repository for gene expression data on normal human tissues. In short, investigations of gene expression represent a major new scientific interest.

Gene Function

In biological perspective, identification of an important gene becomes truly significant only after its function is recognized. This is well acknowledged; in answer to the entry “gene function,” PubMed cited over 60,000 entries on the Internet.

Because the human and mouse genomes are 80% identical, while many single genes are completely identical, studies of mice are widely used.^[43] The use of mice has also the advantage that the function of a gene can be demonstrated by in vitro or in vivo knockout, i.e., experimental gene elimination. Yoshihara et al.^[86] found a significant number of fly homologs of human neurological disease loci; they suggested *Drosophila* as an important disease model for human neuropathology.

There is much debate over the utility of multiple locus association analyses in the identification of genomic regions harboring sequence variants that influence complex traits.^[87] There are new methods of testing the statistical association between haplotypes and a wide variety of traits.^[88] The identification of thousands of genes generated by the various genome projects is a challenge.^[89]

A crucial aspect of studying gene function is identification of the protein formed by the gene in question; determination of protein function is a traditional aspect of biology. The science of protein identification and their systematic, large-scale analysis is “proteomics.” Protein profiles can be correlated with specific effects of disease and with alterations of function.^[90–92] The importance of the subject is well illustrated by the recent creation of a journal entitled “Proteomics.”

The biological utilization of the many types and amounts of information gathered by different methods is aided by the complex science of “bioinformatics,” i.e., the use of computers for the storage or analysis of biological information. Also there is a journal by that name. There is a recent catalog of the computer-based resources that provide access to many of the collections of information on bioinformatics,^[93] and lists of key words and related items.^[94]

Drug Design

Once the functional genomic studies have revealed all pertinent information, i.e., the gene of interest, its biological role, and the dependent protein, one can start to think of the chemical structures that a drug must have to

affect gene function.^[26] There are different methods of virtual screening as discovery tools for lead structure.^[95]

A good example is the development of novel inhibitors of acetylcholinesterase, using a structure-based design approach.^[96] Starting with chimeras of tacrine, the authors conducted a molecular modeling study using the x-ray structure of the apoenzyme; they determined several favored attachment positions and other characteristics. They synthesized several matching compounds and determined their inhibitory potencies. They were found to be in the low nanomolar range.

If the three-dimensional structure of a given protein is known, this information can be directly exploited for the retrieval and design of new ligands. Nuclear magnetic resonance spectroscopy and x-ray crystallography are useful for molecular modeling.^[97] The knowledge of the crystal structure of the target protein or of a model derived from it is very helpful. This information can be used to stimulate thinking of improving an existing ligand, or of developing new alternative bonding skeletons. The features of the protein binding pocket can be translated into queries used for virtual computer screening of large compound libraries or to design novel ligands de novo.^[98] The need for structural information about drug-protein complexes is fundamental for drug discovery.^[98] A leads optimization procedure is described by Williams et al.^[99] The current state of design methodology for inhibitors specifically targeting protein surfaces and computational methods has been reviewed by Zeng.^[100]

Perspectives of the requirements for the development of leads and drugs have been summarized in an overview paper.^[101] The chemical features should be amenable to optimization, the patient situation should be favorable, absorption and other distribution properties should be good. A set of measurable items can help to appraise such determinants.

CONCLUSIONS

There are large-scale efforts in all scientifically advanced countries to promote personalized medicine. This new medicine would leave behind the traditional ways of choosing drugs for treatment, ways that were based on population averages and visual disease diagnostics. Genetic diagnostics would become the fulcrum for clinical decisions. The tasks needed to achieve these changes are enormous, and substantial time for achievement will be required; yet, current scientific knowledge tells us that the goal makes sense, and that major searching efforts are worthwhile. Medical and public perceptions of the hoped-

for changes are problems that need to be addressed in an open discussion.

HISTORY OF DOSAGE FORMS AND BASIC PREPARATIONS

Robert A. Buerki

The Ohio State University College of Pharmacy, Columbus, Ohio, U.S.A.

Gregory J. Higby

American Institute of the History of Pharmacy, Madison, Wisconsin, U.S.A.

INTRODUCTION

The creation and manufacture of dosage forms has been at the center of pharmacy practice for the past thousand years. For American pharmacists of the nineteenth century, *secundem artem*, or the acronym "S.A." in physicians' prescriptions, instructed them to use their special skills "according to the art" of their profession to compound a medicine; it was out of this art, rather than science, that almost all of today's major dosage forms arose. Tablets, capsules, injectables, and oral solutions were all known to pharmacists and physicians a century ago. In addition, there were scores of specialized dosage forms that attempted to meet the medical needs of patients, even if the drugs administered in these doses were ineffective or designed to treat symptoms rather than the underlying disease. The origins of most of these dosage forms are lost in history. For this reason, the authors have elected to forego a contrived narrative tying together the few facts at hand with an equally large amount of speculation about the history of dosage forms. Rather, we have assembled a glossary of terms used in orthodox Western medicine to describe both common and unusual modes of drug administration.

For most of its history, the field of pharmacy was much more concerned with drug preparations than with the resulting dosage forms. Up to the sixteenth century, almost all drugs were derived from plants and were made into preparations that served as the ingredients for medicines; these preparations were called *galenicals*, after the great central figure of Western therapeutics, Claudius Galen of Pergamon (131–201). Strictly speaking, galenicals are pharmaceutical preparations obtained by macerating or percolating crude drugs with alcohol or some other menstruum to remove only the desired principles and leave the inert constituents undissolved. Examples of galenicals include decoctions, extracts, fluidextracts, fluidglycerates, infused oils, infusions, oleoresins, resins, tinctures, and vinegars. The term is used very loosely today to designate any type of simple pharmaceutical preparation, whether it

is an extract of a crude drug or a solution of chemicals. Because galenicals were often administered without alteration, the pursuit of new extraction and other preparative techniques sometimes led to developments in dosage forms as well. The goal of medicine preparers since Galen's time has been to create dosage forms that are stable, free from inert material, therapeutically efficacious, and concentrated to facilitate handling and administration.

Tables 1 and 2 provide a comprehensive classification of ancient and modern pharmaceutical preparations recognized in pharmacopeias and other official and unofficial compendia, but do not make the distinction between dosage forms prepared by maceration or percolation (galenicals) and other chemically or physically similar dosage forms. Preparations are divided into liquids and solids. The liquids are further subdivided as: 1) general aqueous solutions and preparations, 2) sweet or viscid aqueous solutions and preparations, 3) general nonaqueous solutions and preparations, 4) alcoholic or ethereal solutions and preparations, 5) oleaginous solutions and preparations, and 6) parenteral solutions and preparations. The solids are subdivided as: 1) medicated solids, 2) medicated particulate solids, 3) medicated solid applications, 4) oral individual dosage forms, and 5) nonoral individual dosage forms. The dosage forms are arranged alphabetically and include Latin titles and synonyms. The historical development of individual dosage forms is traced to about 1950; it was about then that modern pharmaceutical science was applied in depth to the problems of dosage forms, and the term itself gained general currency in the literature of pharmacy.

DOSAGE FORMS AND BASIC PREPARATIONS

Abstracts: Abstracts are powdered extracts of crude drugs prepared by percolating the drug with an appropriate menstruum, reserving a certain portion, evaporating the weak percolate to a thin extract, blending this extract with the reserve portion and lactose, and evaporating the

Table 1 Liquid pharmaceutical preparations

<i>General aqueous solutions and preparations</i>			
Acids, diluted	Enemas	Milks	Vapors
Aerosols	Fomentations	Solutions	Vinegars
Baths	Gargles	Solutions, irrigating	Washes
Decoctions	Infusions	Solutions, nasal	Washes, mouth
Douches	Inhalations	Solutions, ophthalmic	Washes, aromatic
Draughts	Insessia	Sprays	
Drops	Juices	Suspensions	
<i>Sweet or viscid aqueous solutions and preparations</i>			
Condita	Linctus	Mixtures	Shampoos
Confections	Lohochs	Mucilages	Syrups
Conserves	Lotions	Oxymels	
Honeys	Magmas	Quiddonies	
<i>General nonaqueous solutions and preparations</i>			
Fluidglycerates	Glycerites	Paints, medicinal	
<i>Alcoholic or ethereal solutions and preparations</i>			
Collodions	Elixirs	Juleps	Tinctures
Cordials	Essences	Solutio	Wines
Drops, toothache	Fluidextracts	Spirits	
<i>Oleaginous solutions and preparations</i>			
Balsams	Liniments, dental	Oleates	Petroxolins
Emulsions	Oils	Oleoresins	
Liniments	Oils, infused	Oleovitamins	
<i>Parenteral solutions and preparations</i>			
Ampuls	Injections	Serums	

mixture until dry. The mass is weighed and enough lactose added to make the finished product exactly half the weight of the drug from which it is derived. The resulting product represent twice the strength of the original drug. Although they were convenient for compounding prescriptions, abstracts gained little popularity. Made official in the *United States Pharmacopoeia VI* published in 1880, abstracts were dropped in the next revision (1).

Acetum: See *Vinegars*.

Acids, diluted: Diluted acids are acid preparations, usually 5–10% strength, used for both internal and external medicines. Acids became official with the first *United States Pharmacopoeia* (1820). The term comes from the Latin *acidus* meaning “sharp” or “sour” (2, 3).

Acidum dilutum: See *Acids, diluted*.

Aerosols: Aerosols are a system of finely divided liquid or solid particles dispersed in and surrounded by a gas. The roots of the modern aerosol go back to 1862 and J.D. Lynde, who received a patent for a valve, complete with dip tube, designed to dispense an aerated liquid from a bottle.

In 1899, Helbing and Pertsch added liquefied gases. Patents in the early twentieth century usually were related to spraying perfumes. Aerosol fire extinguishers came into use in the 1930s, and insecticide sprays (bug bombs) appeared during World War II. Introduced in 1947, medical aerosol use increased greatly during the 1950s. In 1952, fewer than half a million such aerosols were produced; by 1963, this figure had risen to almost 40 million (4).

Ampulla: See *Ampuls*.

Ampuls: Ampuls are small, flask-shaped, hermetically sealed glass containers containing a sterile medicinal liquid intended for hypodermic injection, either subcutaneously, intramuscularly, or intravenously. Also, ampul is the class name adopted by the *National Formulary V (N.F.)* (1926) for the solutions in these containers. The ampul was invented in 1886 by the French pharmacist Stanislas Limousin (1831–1887) in response to a need by physicians to conserve their stocks of injectable solutions, which were difficult to transport and deteriorated rapidly due to the development of mold. In his classical essay, “Ampoules hypodermiques; nouveau mode de préparation des solutions hyperdermiques,” published in *Archives of*

Table 2 Solid pharmaceutical preparations

<i>Medicated solids</i>			
Bandages	Electuaries	Lamels	Resins
Cones, medicated	Extracts	Moxa	Silk, oiled
Dressings, medicated	Gums	Papers, medicated	Soaps
Dressings, protective	Inhalants	Papers, waxed	
<i>Medicated particulate solids</i>			
Abstracts	Oil sugars	Salts	Teas
Cucufa	Powders	Salts, artificial	Triturations
Insufflations	Precipitates	Salts, effervescent	
Magisteries	Saccharures	Salts, smelling	
<i>Medicated solid applications</i>			
Applications	Epithema	Ointments, ophthalmic	Rubifacients
Auristilla	Frontalia	Pastes	Sacculi
Cataplasms	Gelatins	Pencils, medicated	Scutum
Caustics	Gels	Plasma	Spasmadraps
Cements	Glycerogelatins	Plasters	Stypes
Cerates	Inunctions	Plasters, adhesive	Swabs
Cerecloths	Litus	Plasters, blister	Vesicatories
Creams	Mulls	Plasters, porous	
Dentifrices	Ointments	Pomatum	
<i>Oral individual dosage forms</i>			
Bacillules	Granules	Pills	Triturates, tablet
Cachets	Masses	Powders, divided	Troches
Capsules	Parvules	Tablets	Wafer envelopes
Capsules, soft	Pastilles	Tablets, hypodermic	Wafers
Dragées	Pearls	Tablets, poison	
Globules	Pellets	Tablets, solution	
<i>Nonoral individual dosage forms</i>			
Bougies	Pessaries	Politzer plugs	Suppositories

Pharmacy (1886), Limousin outlined the essential directions for their manufacture:

These ampoules have the form of a small ovoid balloon. They are terminated by a tapered glass tube, and their capacity is a little greater than one cc.

I sterilize the inside of these small containers, using the method of M. Pasteur, by submitting them in an oven to a temperature of about 200 degrees [Celsius]. I then fill them with the medicated solution, be it by introducing the point of the hot ampoule into the cold liquid, or be it by injecting the hot liquid by means of a small injector at the highest point of the ampoule.

The ampoule being filled, I close it over the oxidation flame by holding the open end of the tube into the uppermost part of the flame.

Although great advances have been made in the techniques and mechanics of ampul production,

Limousin's simple rules capture the basic underlying principles. In the United States, ampuls, or "hermetically sealed containers which are filled with a medicinal liquid in a sterile condition, intended for parenteral use," became official in the *National Formulary V* (1926); that same year, the *United States Pharmacopeia X* included a chapter on sterilization but no monograph for individual ampuls. Iodine Ampuls, N.F., containing Iodine Tincture, *United States Pharmacopeia*, in sealed containers, intended to be broken and the liquid applied topically for the emergency disinfection of cuts or wounds, remained official through the *National Formulary XIII* (1970). The French term *ampoule* came from the Latin *ampulla*, which originally designated an earthen jar container for perfume (2, 4–6).

Antiseptic cottons: See *Dressings, medicated*.

Antiseptic gauzes: See *Dressings, medicated*.

Antiseptic pencils: See *Pencils, medicated*.

Apozemes: See *Decoctions*.

Applicatio: See *Applications*.

Applications: Any preparation for external use (5).

Aqua: See *Waters*.

Artificial salts: See *Salts, artificial*.

Astringent pencils: See *Pencils, medicated*.

Auristilla: Auristilla is a preparation used for medication of the ear canal. The *National Formulary V* (1926) Compound Oil of Hyoscyamus is an illustration of the type, closely resembling the Baumé Tranquille of the French *Codex* (1908) (5).

Bacillula: See *Bacillules*.

Bacillules: Bacillules are rod-shaped lozenges, prepared by massing the lozenge material, rolling it into cylinders or pill pipes, and cutting the cylinders into sections approximately twice the length of the diameter. Licorice lozenges are frequently prepared in this form, a popular example of which was formerly known as Wister's lozenge (see *Troches*) (5).

Bacillum: See *Bougies*.

Balneum: Balneum is a bath for general application (see *Baths*) (5).

Balsams: Balsams are natural solutions of resin in an essential oil, which may also contain benzoic or cinnamic acids. The term has ancient roots in words referring both to spices and to embalming. In premodern times, balsams (*baumé* in French) were any resinous vegetable juices or gums, acquiring their modern meaning in the 1800s. Several official preparations, such as Balsam of Copaiba, do not meet this definition but still carry the name because of their outward similarities with true balsams (1, 7).

Balsamum: See *Balsams*.

Bandages: Bandages are strips or ribbons of muslin gauze or other material employed in surgery for the retention of dressings and for the compression, protection, or support of diseased or injured parts. Bandages may be classified as inelastic, semielastic, elastic, or splint bandages. Inelastic bandages include muslin ribbon or roller bandages, gauze bandages, and

water dressing bandages; semielastic bandages include flannel bandages; elastic bandages include rubber, rubberized, or crepe bandages; splint bandages include plaster-of-Paris bandages and crinoline bandages (gauze stiffened with dextrin) or starch bandages (gauze stiffened with starch paste), used to form the base upon which plaster-of-Paris is applied (5).

Baths: The word baths refers to the external application of water to the body, one of the oldest therapeutic techniques. Although some drugs were added, the simple water bath, or balneum, was most common. In the nineteenth century, when the therapeutic application of water was at its peak, baths were divided into hot or vapor (above 36.1°C), warm (29.4–36.1°C), tepid (18.3–29.4°C), and cold (0–18.3°C). The hot bath was a stimulant; the warm bath was soothing; the tepid bath was for treating skin problems; and the cold bath could be used as a stimulant, tonic, or sedative, depending on the administration technique (8).

Blister plasters: See *Plasters, blister*.

Boluses: Boluses are large pills, over 325 mg (5 grains) in weight. The term comes from the Greek *bolos* meaning “lump” (see *Pills*) (2, 5).

Bougia: See *Bougies*.

Bougies: Bougies are instruments or shaped, solid medications for insertion into the urethra or other body cavities. The term comes from the French *bougie*, signifying a thin wax candle named for the Algerian city, Bougie (2, 5).

Buginarium: A nasal bougie (see *Bougies*) (5).

Cachets: Cachets are lenticular or spoon-shaped rimmed disks pressed from rice-flour wafer sheets, used to administer bitter or nauseating drug powders. The powder is deposited in dry concave cachets, and the rims are moistened with water; empty convex cachets are placed on top, sealing the cachets and enveloping the powder. The term “cachet” is from the French *cache*, “to hide.” The *cachet de pain* was invented by the French pharmacist Stanislas Limousin (1831–1887) in 1873 as an improvement over wafers and wafer envelopes. Limousin also developed a perforated board, accommodating three sizes of cachets, a powder measurer, powder funnels, and wooden “wetter and pressers” to speed extemporaneous cachet production by the pharmacist. A popular brand of cachets and cachet apparatus was manufactured around

1885 under the trade name Konseals by the J.M. Grosvenor Company of Boston around 1885. The Konseal apparatus consists of three perforated, nickel-plated metal plates, hinged together to form a cover plate, a base plate, and a shield plate. Saucer-shaped rice-flour Konseals are pressed into the perforations on the cover and base plates, while the shield plate is folded back over to protect the sealing edges of the Konseals in the base plate. The Konseals in the base plate are filled with powdered drug with the help of special funnels and are tamped down with thimble compressors. The shield plate is lifted, and a moistened roller is passed over the edges of the empty Konseals in the cover plate, which is closed over the base plate, sealing the Konseals. The Konseals are made of thinner material than ordinary cachets, and the finished product is less bulky and neater in appearance. Johann Schmidt later introduced rimless Dry Seal Cachets resembling flattened capsules, which were sealed by pressure without moistening (see *Wafers*) (2, 4, 5).

Cachets, dry seal: See *Cachets*.

Caementum: See *Cements*.

Cambric, oiled: See *Silk, oiled*.

Capsula: See *Capsules*.

Capsula amylacea: Starch capsule (see *Cachets*).

Capsula dura: Hard capsule (see *Capsules*).

Capsula gelatina: Gelatin capsule (see *Capsules*).

Capsula mollis: Soft capsule (see *Capsules, soft*).

Capsules: Capsules are telescoping, interconnecting shells of hard gelatin and sugar used for the administration of solids, masses, and liquids. The term comes from the Latin *capsula*, which is the diminutive of *capsa*, meaning “box.” Successor to the soft capsules invented by the French pharmacist François Mothes in 1833, the telescoping hard gelatin capsule was invented and patented in 1847 by James Murdoch of London. In the United States, the New York firm of H. Planten manufactured two-part capsules sometime after 1836, but their usefulness was impaired by their poor fit. In 1863, the firm developed jujube paste capsules intended for dispensing powders alone, offering them to the trade before 1870. Another manufacturer, Dundas Dick, experimented in the same direction and secured a patent on cone-shaped capsules in 1865. Twelve years later, inspired by reports from Italy,

the Detroit pharmacist F.A. Hubel made molds of iron wire mounted in blocks of wood, which could be dipped in a gelatin solution. Using pins of different diameters for the body and cap allowed Hubel to produce capsule sections which would telescope into each other, producing a small cylinder closed at both ends—the prototype of the modern hard gelatin capsule. Hubel sold his entire output to Parke, Davis & Co. in 1875, securing the first in a series of patents in 1877. Despite this protection, several small competing firms soon emerged that made capsules for other companies to sell or for their own sales organizations, most of which were consolidated by James Wilkie into the U.S. Capsule Company. Around 1901, this firm and its subsidiary, the M.L. Capsule Company, were purchased by Parke, Davis & Co., which expanded and improved its manufacturing processes under Wilkie’s supervision. Wilkie is also credited with introducing phosphorbronze wire for capsule molds, a material superior to iron and one which remained in use until replaced by stainless steel in the 1930s. Capsule manufacturing received its greatest impetus in the 1920s when automatic filling devices were perfected. Pharmacists extemporaneously fill capsules at the prescription counter by “punching” capsule bodies into a smooth layer of medicated powder and filler at a uniform level of compression, replacing the caps, and checking the weight of the filled capsule (see *Capsules, soft*) (2, 9–11).

Capsules, elastic: See *Capsules, soft*.

Capsules, enteric-coated: See *Enteric-coated doses*.

Capsules, gelatin: See *Capsules*.

Capsules, glutoid: See *Enteric-coated doses*.

Capsules, hard: See *Capsules*.

Capsules, soft: Soft capsules are elastic globular shells of gelatin, containing sufficient glycerin to retain permanent flexibility, and intended primarily for the administration of irritating or nauseating oily liquids. They were invented in 1833 by French pharmacist François Mothes; an improved capsule was patented by Mothes and Joseph Dublanc the following year and perfected in 1840 by the court apothecary Adolph Steeger of Bucharest. Soft capsules are easier to swallow than hard capsules and are desirable for administering large volumes of liquids. The original Mothes capsules were hollow globes of soft gelatin with an opening at the top for filling. Once filled, the capsules are sealed with a drop of hot gelatin. In 1846, Giraud introduced olive-shaped elastic capsules with an elongated neck, made by dipping molds into a warm

glycerogelatin solution. After drying, the molds were stripped and the capsule necks sealed for future use. Pharmacists cut off the necks of the capsules as needed, filled them with a dropper or syringe, and sealed them with a drop of warm glycerogelatin or the blade of a hot spatula. The first official formula for the manufacture of soft gelatin capsules appeared in the French *Codex Medicamentarius* of 1866 (see *Capsules*) (4, 5, 10, 5, 12).

Capsules, starch: See *Cachets*.

Carbasus: Gauze see *Dressings, medicated*.

Cataplasma: See *Cataplasms*.

Cataplasms: Cataplasms are moist substances intended for external application and are of a consistency as to accommodate themselves accurately to the surface to which they are applied, without being so liquid as to spread over the neighboring parts, or so tenacious as to adhere firmly to the skin. Cornelius Celsus (50–25 B.C.) described early Roman softening ointments or malagma (from the Latin *malasso*, meaning “soften”) made by boiling flour in water to make a stiff paste that was admixed with melted gums or wax. The word “cataplasm” derives from two Greek words, *kata*, meaning “down,” and *plasso*, meaning “to mold.” Modern cataplasms are made by rubbing together glycerin and a dry powder, such as kaolin, to make a very firm mixture. Since cataplasms (or poultices) were commonly used in the United States in domestic practice and made in the home, they were rarely prepared by pharmacists. A kaolin cataplasm became official in the *United States Pharmacopeia VIII* (1905) but was transferred to the *National Formulary IV* in 1916 (2, 4, 5, 13).

Caustic pencils See *Pencils, medicated*.

Caustics: Caustics are local remedies that destroy life on the part of the body to which they are applied. The term comes from the Greek *kaustikos*, meaning “to burn.” The strongest common caustic (*causticum commune acerrimum*) was potassium hydroxide, or caustic potash, used to form issues on the body or to open abscesses. The *United States Dispensatory* (1836) advised that the most convenient mode of employing a caustic to form an issue was:

To apply to the skin a piece of linen spread with adhesive plaster, having a circular opening in its centre corresponding to the intended size of the issue, and then to rub upon the skin within the opening a piece of the caustic previously moistened

at one end. The application is to be continued until the life of the part is destroyed, when the caustic should be carefully washed off by a wet sponge or wet tow, or neutralized by vinegar.

Caustic potash was sometimes used to remove strictures in the urethra or, in solution, as an application to the spine in treating tetanus. A contemporary caustic, silver nitrate, was described in the seventh century A.D. by Geber; it remains official in the *United States Pharmacopeia* as Fused Silver Nitrate. Christopher Glaser, apothecary to Louis XIV, first prepared it in sticks for use as a caustic (2, 5, 13).

Cements: The 7th edition of the *National Formulary* (1942) listed a formula for a Cement of Zinc Compounds and Eugenol, which was widely used by dentists as a temporary filling. The cement was supposed to exert a sterilizing effect and protect the dentine from further destruction. The formula passed out of the *National Formulary* with its 9th edition (1950) (14).

Cerates: Cerates are unctuous substances for external application as dressings for inflamed surfaces. Derived from the ancient Greek *keroma* (from *keros*, “wax”), cerates are generally made with oil, lard, or petrolatum as a basis, with sufficient wax, paraffin, spermaceti, or resin added to raise the melting point of the oils and fats employed. Cerates should be of such consistency that they may be easily spread at ordinary temperatures upon muslin or a similar material with a spatula and, yet, not so soft as to liquefy and run when applied to the skin. The most widely used cerate was Ceratum Cantharidis, a blistering plaster made of Spanish flies that was official in the *United States Pharmacopeia* and later in the *National Formulary* until 1950 (see *Plasters, blister*) (5).

Ceratum: (See *Cerates*).

Cerecloths: Cerecloths are an early form of dipped plasters, described by William Salmon in his *Pharmacopoeia Londonensis* (1691), used chiefly to lay upon issues—small ulcers produced by caustics or cutting, the discharge from which was encouraged to fulfill certain therapeutic indications. Also known as spasmodraps or sparadraps (see *Plasters*) (15).

Cereolus: A cereolus is an urethral bougie (see *Bougies*) (5).

Charta: The term comes from the Greek *chartes* or papyrus (see *Papers, powder*) (2).

Charta amylacea: Starch papers (see *Cachets*).

Charta cerata: (see *Papers, waxed*).

Chrisma: A salve (see *Ointments*) (5).

Clysters: See *Enemas*.

Coatings, pill: Rhazes (850–923) used a mucilage of psyllium seed to coat offending pills; a century later, Avicenna (980–1037) introduced silver and gold coatings for pills not merely to mask bad taste but to enhance the supposed medicinal effect. Later, the influential seventeenth-century Parisian physician and pharmacist Jean de Renou recommended that pills with a bitter taste should be gilded and mixed among some powdered spices. Coating pills with gold and silver leaf was commonly practiced in France, other parts of Europe, and the United States until well into the nineteenth century but then fell into disuse. Mohr, Redwood, and Procter's classic *Practical Pharmacy* (1849) reported that foil-coated pills were "still occasionally administered, but much less frequently than formerly." Sugar-coated and gelatin-coated pills had their first acceptance as an indirect consequence of the invention of the gelatin capsule. In 1838, M. Garot, a Parisian pharmacist, coated offending pills with gelatin. A year earlier, the French pharmacist Labelonie had recommended that pills of cubeb and copaiba be covered with sugar, a process that was patented by Adolphe Fortin of Paris in 1837. Over the next several years, other French pharmacists (Deschamps, Bousquet, Mayer, and Roman) secured patents for coating pills with various combinations of sugar, honey, and acacia. By 1862, England's Bernard Proctor could list 45 distinct processes for coating pills with a variety of substances. In the United States, the first manufacture of sugar-coated pills was associated with the patent-medicine industry, probably as early as 1845. New Yorkers Cornelius V. Clickener and Zadoc Porter and a Philadelphia physician named Swayne all claimed to be the "inventor" of the sugar-coated pill but doubtlessly adapted French technology. By 1857, five different sugar-coated patent-medicine pills were available to American pharmacists, but no process was available for pharmacists who wished to sugar-coat pills extemporaneously. About that same time, Henry A. Tilden and William R. Warner independently developed processes for manufacturing sugar-coated pills and began selling them in bulk; in 1866, Warner began manufacture under his own firm name, William R. Warner & Company. That same year, Henry Wathew of Philadelphia developed and patented a prototype of the angled coating pans still employed today.

By the mid-1870s, a variety of small mechanical coating pans were available to American pharmacists, although the quality of the extemporaneous coatings that could be achieved was generally inferior to that of the manufactured variety, which caused pharmacists to relinquish the practice (16–18).

Coatings, tablet: After the introduction and acceptance of the compressed tablet as a dosage form superior to pills, the same techniques that had been employed for sugar-coating pills were adapted to tablets (see *Coatings, pill*). Moreover, compression coating techniques were also introduced by Charles Carter of Philadelphia as early as 1858. In 1896, P.J. Noyes invented an apparatus incorporating a movable die cavity into which the coating material was fed; the powder was compressed to form a coating around the pill or tablet by striking the upper punch with an automatic hammer. The following year, Noyes patented an improved machine that not only applied the coating but also performed the preliminary compression of the tablet. F.J. Stokes received a patent for a similar machine in 1917, although the compression coating of tablets did not become widely adopted until the 1950s (18).

Collodions: Collodions are liquid, external preparations with a base of pyroxylin dissolved in a mixture of alcohol and ethyl oxide or similar solvent. They were used medicinally soon after the discovery of gun cotton by Schoebein in 1846, first as a surgical dressing by Maynard in 1847 (19).

Collodium: See *Collodions*.

Collunarium: See *Solutions, nasal*.

Collutorium: See *Washes, mouth*.

Collyrium: See *Solutions, ophthalmic*.

Compressed pills: See *Tablets*.

Compressed tablets: See *Tablets*.

Condita: Condita are comprised of candied or preserved roots or fruits. They are made by boiling the plant parts until tender, soaking them in hot syrup, and then pouring off the syrup; the procedure was repeated several times, reusing the syrup after boiling it down to a thick consistency. Condita can also be a compound of wine, honey, and spices (often pepper). Condita are also known as confitures or sweetmeats (18, 20).

Cones, medicated: Cones are light, porous hemispherical masses of sucrose and egg albumin, used as a vehicle for homeopathic medications. The cones, also called disks, are designated (in millimeters) according to size by the diameter of the base. The common size (No. 6) should absorb about 2 drops of dispensing alcohol. Cones are medicated by adding a sufficient quantity of the dilution to saturate them and pouring off the excess liquid (5).

Confectio: See *Confections*.

Confections: Confections are saccharine, soft solids, in which one or more medicinal substances are incorporated to provide an agreeable form of administration and a convenient method for preservation. In the thirteenth century, some apothecaries were called *confectionarii* from *confectio* meaning “a composition.” Confections are made by adding medicinal ingredients in either the form of a smooth paste, a fine powder, or a liquid to a basis of finely powdered sugar. Confection of Rose and Confection of Senna were official in the *National Formulary* through the 5th edition (1926) (2, 5).

Confitures: See *Condita*.

Conserva: See *Conserves*.

Conserves: Conserves are confections prepared from fresh medicinal agents and refined sugar, beaten into a uniform mass. The *United States Dispensatory* (1836) noted that “as active substances even thus treated undergo some change, and those which lose their virtues by desiccation cannot be long preserved, the few preserves now retained are intended rather as convenient vehicles of other substances, than for separate exhibition.” Conserves are also known as preserves (also see *Confections*) (5, 13, 20).

Cordiale: See *Cordials*.

Cordials: Cordials are sweetened alcoholic preparations of high alcoholic content. They are also a tonic medicine formulated to stimulate the heart (5, 20).

Cottons, antiseptic or medicated: See *Dressings, Medicated*.

Creams: Creams are semisolid emulsions, usually medicated, intended for external application. The term “cream” has been used to refer to a wide variety of opaque, soft semisolids or thick liquids intended for external use. The *British Pharmacopoeia* classifies creams as medicated

liquid emulsions consisting of a mixture of anhydrous lanolin, olive oil (or other fixed oil), and lime water; milk of magnesia is often referred to as a cream, and many cosmetic preparations are called creams. Claudius Galen (131–201) prepared the first *unguentum refrigerans* or “cold cream,” an ointment containing olive oil, rose oil, white wax, and a small quantity of water. This was a prototype for other cosmetic ointments introduced by Johann Mesue, Jr., in the thirteenth century. A modern version, consisting of almond oil, spermaceti, white wax, and rose water, passed into the *United States Pharmacopoeia* as “Rose Water Ointment” or “Galen’s Cerate.” Pharmaceutical creams became official with the introduction of the formula for a “Sun Cream” in the *National Formulary VIII* (1946), a product designed to prevent sunburn but permit tanning. Cosmetic creams, which are usually not medicated, include preparations classified as all-purpose creams, baby creams, barrier creams, bleaching creams, cleansing (or rolling) creams, cold (or fatty) creams, foundation (or vanishing) creams, hair creams, and hand creams (4, 5, 21).

Cremor: See *Creams*.

Cucufa: Cucufa is a cap, dusted on the inside with medicinal powder, which is applied to the head to strengthen the brain (22).

Curatio: See *Dressings, medicated*.

Decoctions: Decoctions are a solution of vegetable drugs, obtained by boiling the substances in water; they are also known as apozemes (8).

Decoctum: See *Decoctions*.

Dental liniments: See *Liniments, dental*.

Dental wax: See *Drops, toothache*.

Dentifrices: Dentifrices are powders, pastes, washes, or medicated soaps used for cleaning the teeth. Dentifrices are usually flavored with aromatic oils, frequently contain soap, almost always some form of chalk, and are applied with a toothbrush. The *National Formulary* carried official formulas for a liquid dentifrice through its 5th edition (1926) and a powder dentifrice through its 11th edition (1960) (5).

Dentifricium: See *Dentifrices*.

Dentilimentum: See *Liniments, dental*.

Dermatologic pastes: See *Pastes*.

Diluted acids: See *Acids, diluted*.

Disks: See *Cones, medicated*.

Dispensing tablets: See *Tablets, solution*.

Douches: Douches are a column of fluid, of a certain nature and temperature, allowed to fall on a part of the body. Air can also be used as a douche (20).

Dragées: Dragées are candied or preserved roots and fruits described by the Arab Najm ad-dyn Mahmoud in the eighth century and reintroduced in the eighteenth century by the famous French pharmacist Moyse Charas (see *Confitures*). By the middle of the nineteenth century, the term was extended to include a type of sugar-coated pill formed by repeatedly shaking slightly moistened, tiny 6-mg (1/10 grain) sugar granules (or nonpareils) in a basin of finely powdered drug mixed with sugar. After a sufficient number of layers had been built up, the dragées would receive a final coating of sugar or copal and tolu balsam, a painstaking process described by Ernest Agnew in the *American Journal of Pharmacy* (1870) (see *granules*) (18, 23).

Draughts: Draughts are liquid medicines usually prepared to be taken in a single dose or "draught." Draughts are also known as potions (5).

Dressings, medicated: Medicated dressings are external applications resembling ointments in consistency but remaining semisolid at body temperature. Paraffin Dressing, formerly official in the *National Formulary VI* (1936), was employed as an air-excluding, soft, pliable, analgesic, splint-like covering for surfaces denuded by burns. A wide range of materials have been used as coverings or protectives to apply heat or medicaments to a diseased or injured part, to prevent wound infection, and to absorb and prevent decomposition of wound discharges. Antiseptic or Medicated Cottons include borated cotton, iodoform cotton, iodized cotton, and styptic cotton; Antiseptic or Medicated Gauzes include borated gauze, corrosive sublimate gauze, carbolated gauze, iodoform gauze, and picric acid gauze; Antiseptic or Medicated Lints include borated lint; Cellulose Waddings or wood wools include moss, peat, sawdust, jute, and oakum or marine lint. See the *British Pharmaceutical Codex* (1924) for representative formulas (also see *Bandages* and *Dressings, protective*) (5, 24).

Dressings, protective: Protective dressings are comprised of a wide range of materials employed as wound coverings, either to shield the parts from external infection or to prevent the escape of fluids contained in the dressing. Protective dressings are also used as a covering for poultices and for the retention of heat. Common protective dressings include oiled silk, oiled muslin or cambric, waxed paper, gutta percha tissue, rubber dams, mackintosh or jaconet, and rubber sheeting (5).

Drops: Drops are pharmaceutical mixtures meant to be given in small amounts. Before the twentieth century, the term applied to solutions used in small quantities expressed in "drops." These were commonly strong medicines "dropped" into water, such as Vinegar of Opium or "black drop." In modern pharmacy, the term became more associated with the need to get a medicine into an appropriately small amount of vehicle for application to the eye (ophthalmic), ear (otic), or passages of the nose (nasal). As a dosage unit, the drop is troublesome because it can vary greatly in size, depending on the size of the dropper orifice and the surface tension of the liquid. The *United States Pharmacopeia IX* (1910) set the official dropper at 20 drops per gram of water at 15°C \pm 10% (3, 20).

Drops, ear: See *Drops*.

Drops, eye: See *Drops*.

Drops, nose: See *Drops*.

Drops, toothache: Drops for toothache are comprised of a solution of phenol in oil of cinnamon and methyl salicylate. The solution entered the *National Formulary V* (1926). A mixture of phenol, creosote, or volatile oils dissolved in paraffin, with a few filaments of cotton added, and molded into sticks constitutes Dental Wax (5).

Ductum: See *Douches*.

Dry seal cachets: See *Cachets*.

Ear drops: See *Drops*.

Eclectus: See *Linctus*.

Eclegma: See *Lohoch*.

Effervescent salts: See *Salts, effervescent*.

Elaeosacchara: See *Oil sugars*.

Elastic capsules: See *Capsules, soft*.

Electuaries: Electuaries are confections prepared from dried medicinal agents, especially powders, combined with syrup or honey in order to render them pleasant to the taste and convenient for internal use. The *United States Dispensatory* (1836) noted that electuaries “should not be so soft ... as to allow the ingredients to separate, nor so firm ... as to prevent them from being swallowed without mastication.” French writers recommend using brown sugar syrup to prepare electuaries, because it is less apt to crystallize than that made from refined sugar. The term comes from the Greek words *ek*, meaning “out,” and *leichein*, “to lick” (2, 13) (see *Confections*).

Electuarium: See *Confections*.

Elixirs: Sweetened, hydroalcoholic, flavored liquid medicines, which became popular in mid-nineteenth-century America. The word is derived apparently from the Arabic *al-iksir*, which is an Arabic form of the Greek, *xirion*. Originally the term meant “dry powder.” Elixirs came into medicine through their connection with alchemy. Elixir Rubrum, one of the most renowned alchemical compounds, could supposedly turn mercury to gold or prolong life. The term was picked up by followers of Paracelsus (1493–1541) and became applied to liquid preparations. European elixirs were generally bitter. One of the first American elixirs was Cordial Elixir of Quinine (ca. 1838), made by John T. Heinitch of Lancaster, Pennsylvania. After the Civil War an “elixir craze” began, which led to scores of companies competing for business. As much as any other development, the “craze” led to the publication of the first *National Formulary* in 1888 (25, 26).

Embrocatio: See *Liniments*.

Emplastrum: See *Plasters*.

Emulsions: Emulsions are a preparation consisting of two immiscible liquids, usually water and oil, one of which is dispersed as small globules in the other. Before the late seventeenth century, the term only applied to natural emulsions, such as ground almonds and water, which resembled milk. In 1674, a physician named Grew reported the preparation of oils and egg yolk to the Royal Society of Great Britain. In the 1700s, other emulsions were made with acacia, honey, tragacanth, and other natural emulsifying agents. In the 1800s, the wet-gum (ca. 1850) and dry-gum (ca. 1870) methods were established as standard preparation techniques. Interest in medicinal

emulsions peaked in the early to mid-twentieth century with the development of several new emulsifying agents. Originally listed under “Mixtures” in the *United States Pharmacopeia*, they are a separate entry in the 7th revision (1890) (4).

Emulsum: See *Emulsions*.

Enemas: Enemas are injections of liquid, either plain or containing drugs, into the rectum and colon to empty the lower intestine or to introduce food or medicine for therapeutic purposes. Enemas are one of the most ancient and widely used methods of introducing therapeutic substances into the body. The origins of use are lost in prehistory, but written records in Egypt before 1000 B.C. describe enemas being used to both cleanse the bowel and administer medicines. These early enemas consisted of three parts: a vehicle (usually water, beer, or milk), an emollient (usually oil or honey), and a medicinal substance. The Greek historian Herodotus (fifth century B.C.) attributed the general good health of the Egyptians to their use of enemas and claimed they had achieved their expertise through their experiences with injecting embalming fluids via the anus. Pliny (first century A.D.), however, argued that the Egyptians had learned to administer enemas by watching the ibis use its curved bill to inject itself with Nile River water as a purge. Hippocrates recommended enemas to treat fevers and constipation. Other authors of antiquity, such as Galen and Oribasius, wrote at length about what substances could be introduced via enemas. Enema apparatus was first described in detail by Arabian physicians of the eleventh and twelfth centuries. Albulcasis described a device made of an anal tube or funnel attached to a bag made from an animal bladder or sheep skin. The metal piston syringe came into use in the 1400s and supplanted these clumsy bags. The enema syringe soon became the object of much medical ingenuity, particularly in France. In 1480, Louis XI suffered a severe stroke and recovered, giving credit to the enemas he had received, beginning a 400-year period of fascination with the enema among the French, who refined the syringe apparatus. Molière referred to enemas repeatedly in his works, and Ambrose Paré devised a syringe instrument about 1580 that allowed enema self-administration. During the seventeenth century, other special apparatus were designed to allow administrations of tobacco smoke via enemas. The Dutch anatomist Regner de Graaf completed the first book-length study of enemas in 1668. In the mid-eighteenth century, gum rubber began to be used in enema apparatus, replacing skin bags. In 1820, John Read developed a two-way syringe with ball valves (the first modern stomach

pump), which was also used for enemas. Spring-loaded syringes and other advances followed, but by the late nineteenth century the dangers of improper enema use became apparent, especially the consequences of high-pressure administration. By the mid-twentieth century, enemas were again administered with simple funnels and gravity, a reflection of their prehistoric origin. Enemas are also known as clysters or glysters (27, 28).

Enteric-coated capsules: See *Enteric-coated doses*.

Enteric-coated doses: Enteric-coated doses are dosage forms that have been coated or chemically treated to prevent disintegration in the stomach but which disintegrate in the intestinal tract. Enteric coating is employed when the medicinal substances would be decomposed or rendered inactive by gastric enzymes or when they would irritate the gastric mucosa. The *Pacific Medical and Surgical Journal* (1867) noted that collodion protects pills from dissolving in the stomach, but gastric insolubility as a basis for medication is generally credited to the German dermatologist Paul Unna, who introduced keratin-coated pills in 1884; Ceppi introduced salol as an enteric coating in 1891. Glutoid capsules are a special form of enteric coating prepared by subjecting soft or hard gelatin capsules to the action of formaldehyde until they become insoluble in the stomach but not in the intestine. The hardening process was developed in Switzerland by Weyland in 1895 and patented by Hausmann in Germany that same year. Pharmacists have extemporaneously coated capsules, pills, and tablets with salol, keratin, casein, and shellac, or with a mixture of *n*-butyl stearate, carnauba wax, and stearic acid to create enteric coatings. Early patented enteric coatings included keratin (Pohl, Germany, 1885), fat-covered capsules enclosed in membranous sacs (Webb and Webb, Great Britain, 1906), and benzoin-coated capsules (Horigan, 1928). Later patented coatings utilized cellulose nitrate and acetate (Volwiler, 1928), cellulose esters and ethers with saponifiable organic compounds (Glaessner, Austria, 1931), ammoniacal bleached shellac (Wruble, 1933), stearic acid, carnauba wax, petrolatum, elm bark, and agar (Miller, 1935, and Worton, 1938), and abietic, oleic, and benzoic acids with methyl abietate (Eldred, 1937). Since 1940, research on enteric coatings has focused on the synthesis of resinous polymers, which are insoluble in acids, such as cellulose acetate phthalate (Hiatt, 1940) and a glycerol-stearic acid-phthalic anhydride ester (Volweiler and Moore, 1940) (4, 5, 12, 17).

Enteric-coated pills: See *Enteric-coated doses*.

Enteric-coated tablets: See *Enteric-coated doses*.

Epispastics: Epispastics are local remedies, the application of which produce a serous discharge beneath the cuticle, forming a blister. Epispastics are also known as vesicatories (13).

Epithema: Epithema consists of topical applications other than ointments or plasters. Liquid epithema include fomentations, soft epithema include cataplasms, and dry epithema include bags filled with dried drugs (20).

Escharotica: See *Caustics*.

Escharotics: Caustic applications (see *Caustics*) (5).

Essences: The term essences sometimes refers to a volatile oil or to a simple tincture; most often, the term is used interchangeably with spirits (20).

Essencia: See *Essences*.

Extracta: See *Extracts*.

Extracts: Extracts are either pasty or semisolid masses or dry, solid, or powdered products prepared by exhausting drugs with appropriate solvents, carefully evaporating the products to fixed standards. An extract is intended to preserve the useful constituents of a drug in a concentrated, relatively uniform, permanent condition, and in a form suitable for medication. The *Edinburgh Pharmacopoeia* (1817) and *Dublin Pharmacopoeia* (1826) distinguish between extracts prepared from infusions, decoctions, or tinctures, and those prepared from the expressed juices of plants, calling the latter *succi spissati* or inspissated juices. Three forms of extracts are recognized: semiliquid or those of syrupy consistency; plastic masses known as pilular or solid extracts; and dry powders known as powdered extracts (4, 5, 13).

Extractum: See *Extracts*.

Eye Drops: See *Drops*.

Eye Washes: See *Solutions, ophthalmic*.

Fluidextracts: Fluidextracts are concentrated liquid preparations representing the therapeutically active principles of vegetable drugs. They are formulated in such a way that the activity of one gram of the drug is contained in one milliliter of the fluidextract. They are generally prepared by some form of percolation, using

alcohol in the menstruum. Fluidextracts first became official in 1850 when five were entered in the *United States Pharmacopoeia* by their heyday in the late nineteenth century, almost 100 were official. Joseph Remington called fluidextracts “American preparations,” because they were developed by such native pharmaceutical scientists as William Procter, Jr., and Edward Squibb. Fluidextracts were perhaps the ultimate galenical class because of their permanence, concentrated form, and uniform relationship between the strength of the extract and the drug it contained. With the dominance of synthetic chemical drugs in the twentieth century, fluidextracts all but disappeared, except for those used for flavoring purposes (1, 19, 29).

Fluidextractum: See *Fluidextracts*.

Fluidglycerates: Fluidglycerates are a class of fluidextracts in which a mixture of glycerin and water is used as the primary menstruum during percolation instead of alcohol and water. The preparation of these extracts was suggested by Beringer in 1908. They were briefly official from the 5th–7th editions of the *National Formulary* (1926–1942) (3).

Fluidglyceratum: See *Fluidglycerates*.

Fomentations: Fomentations consists of an external application of cloths dampened with hot water or a medicinal decoction. Narcotic drugs were sometimes used. Dry fomentations were heated bricks wrapped in cloth and applied externally (5, 20).

Fomentum: See *Fomentations*.

Fotus: See *Fomentations*.

Frontalia: Medicines applied to the forehead (20).

Gargarisma: See *Gargles*.

Gargles: A gargle is a liquid medicine intended to be retained in the mouth and placed in contact with the back of the throat by throwing back the head and agitated by air released from the larynx (20).

Gauzes, antiseptic or medicated: See *Dressings, medicated*.

Gelatin capsules: See *Capsules*.

Gelatina: See *Gelatins*.

Gelatins: Gelatins are semisolid gelatinous preparations for internal or external use (5).

Gelatum: See *Gels*.

Gels: Gels are semisolid organic or inorganic colloids rich in liquid, consisting of hydrated threads or granules of the dispersed phase intimately associated with the dispersion medium. Although Francesco Selmi studied inorganic colloids in the 1840s, modern colloid science began in 1861 with the work of Thomas Graham, who investigated diffusion and dialysis and introduced such terms as colloid, glue, sol, gel, peptization, and syneresis. In the early 1900s, Freundlich introduced the terms *lyophilic* and *lyophobic* to describe colloids in which the dispersed phase has a high or a low affinity, respectively, for the dispersion medium. In 1950, Weiser divided gels into inorganic gels, which include gelatinous precipitates (such as Milk of Magnesia) and inorganic jellies (such as Bentonite Magma), organic gels or jellies (such as Pectin Paste), and crystalline or amorphous jellylike networks in which both solid and liquid phases are continuous (see *Magma*) (4).

Globules: Globules are spheres of sugar (see *Pills*). They can also be round or oval glycerogelatin capsules (see *Pearls*) (5).

Glutoid capsules: See *Capsules, glutoid*.

Glycerinum: See *Glycerites*.

Glycerites: Glycerites are solutions of medicinal substances in glycerin introduced in the 5th revision of the *United States Pharmacopoeia* (1873). Glycerites afford a rapid and simple method of making aqueous solutions of phenol, tannic acid, tar, and other substances that are not otherwise easily soluble. This class of preparations is called glycerins in Great Britain (4, 5).

Glyceritum: See *Glycerites*.

Glycerogelatins: Glycerogelatins are soft, medicated masses, usually molded into the form of blocks, which melt at body temperature and have as a base a mixture of gelatin, glycerin, and water; Glycerated Gelatin United States Pharmacopoeia is generally used as a base. At the time of application, the blocks are melted, and the liquid applied to the skin with a soft brush. Four glycerogelatins were introduced into the 3rd edition of the *National Formulary* (1906), and a general formula remained official

through the 8th edition (1946). Under the title *Gelatinum*, the *British Pharmaceutical Codex* (1922) included preparations that were either similar to glycerogelatin, that more closely resembled dermatologic pastes, or that were intended for internal administration and called jellies (4, 5).

Glycerogelatinum: See *Glycerogelatin*.

Glysters: See *Enemas*.

Gossypium: Cotton (see *Dressings, medicated*).

Granula: Granular effervescent salts (see *Salts, effervescent*).

Granules: Granules are small spheres of sugar pellets that are saturated with liquid medication before being swallowed. They can also be very small pills of 0.06 g or less, sometimes called parvules, made by slightly moistening sugar granules (or nonpareils) with a syrup in which an active ingredient has been dissolved. Granules containing 1 mg of powerful medications, such as arsenious acid or aconite, found favor among physicians in Europe, particularly in Italy, because they provided powerful drugs in small, precise doses (see *Dragées*; also see *Pills*) (4, 23).

Gums: Gums are mucilaginous, amorphous, transparent, or translucent glucosidal principles of plants used internally (as demulcents or expectorants), externally (as emollients or protectives), or for their emulsifying action. Three distinctive types of gums are recognized: arabin, which is completely soluble in water; bassorin and cerasin, which are partially soluble or swell in contact with water; and mucilages and pectins, which swell to form jellies. Many gums are complex mixtures of several of these types (5).

Guttae: See *Drops*.

Hard capsules: See *Capsules*.

Haustus: See *Draughts*.

Homeopathic tinctures: See *Tinctures*.

Homeopathic triturations: See *Triturations*.

Honey: Preparations with honey as the vehicle (8).

Infused oils: See *Oils, infused*.

Infusions: Infusions are aqueous solutions obtained by soaking vegetable drugs in cold or hot (not boiling) water (8).

Infusum: See *Infusions*.

Inhalants: Inhalants are products consisting of finely powdered or liquid drugs that are carried into the respiratory passages by the use of powder blowers or low-pressure aerosol containers holding a suspension of the drug in a liquefied propellant. A dry inhalation is a product consisting of finely powdered drugs that are carried into the respiratory passages with the help of special devices. Inhalants can also refer to drugs or a combination of drugs which, by virtue of their high vapor pressure, can be carried by an air current into the nasal passages where they exert their effect. In the latter form of inhalant, the drug is absorbed on fibrous material and enclosed in an inhaler—a plastic or metal tube fitted with a cap to prevent loss of medicament when not in use. The patient removes the cap, inserts the nasal tip into a nostril, and breathes the air drawn through the inhaler to obtain the drug (4).

Inhalatio: See *Inhalations*.

Inhalations: Inhalations are medicinal agents administered by breathing in gases and vapors. A wide variety of techniques and purposes fall under this category. The isolation of pure gases by Priestley, Scheele, and others in the late eighteenth century motivated Thomas Beddoes to found the Pneumatic Institute (1798) in England to treat lung diseases. The gases used for inhalation therapy included oxygen, nitrous oxide, and ether. Gases were applied as surgical anesthesia in the 1840s largely through the efforts of the Americans Crawford Long, Horace Wells, and W.T.G. Morton; their innovations were the first great contributions to medical science by citizens of the United States. The therapeutic use of gases continued throughout the nineteenth century, especially for the treatment of tuberculosis. During this period, devices were designed to vaporize liquid drugs with steam for the treatment of lung disorders. The first apparatus developed to atomize medicinals, made by Berson in 1860, was a combination inhaler and atomizer operated by steam that was generated by heating water in a closed vessel. These devices were quite popular for home use, and their modern counterparts remain a part of home health care. The term *inhalation* has also been applied to preparations more properly called inhalants, such as Compound Eucalyptus Inhalation, or sprays, such as

Epinephrine Inhalation (see *Inhalants and sprays*) (24, 30, 31).

Inhalations, dry: See *Inhalants*.

Injectio: See *Injections*.

Injections: Injections are sterile solutions or suspensions used for administering pharmaceutical preparations by intravenous, subcutaneous, intramuscular, and intraspinal injection. The term *injections* is also the class name adopted by the 5th edition of the *National Formulary* (1926) for solutions in ampuls intended for hypodermic injection. Although ancient humans may have invented the concept of introducing drugs through punctures in the skin by attempting to recreate the effects of venomous snake and insect bites through the use of poisoned arrows, perhaps the first introduction of medication through the skin for medicinal purposes was inoculation for smallpox. Human inoculation with the smallpox virus by pricking the body with needles dipped in pus from an active case of the disease was practiced for centuries among people of the Orient but was only introduced into Western medicine about 1717. In 1796, Edward Jenner (1749–1823) performed his first vaccination with material from a cowpox sore. In 1657, Sir Christopher Wren was the first to inject a drug intravenously, a practice successfully adopted by the English practitioner Johan D. Major in 1662 under the title “*chirurgica infusoria*.” Physicians experimented with the injection of water, opium, arsenic, cinnamon, oil of sulfur, and other substances with limited and often fatal results. Injections of purging medicines, such as jalap resins, were particularly popular in the treatment of syphilis. Nevertheless, the successful utilization of intravenous injection awaited the proof of the germ theory of disease and the discovery of sterile methods by Pasteur, Koch, Lister, and others in the latter half of the nineteenth century; the introduction of the hypodermic syringe, which was suggested by Charles G. Pravez of Lyons in 1853, popularized by Alexander Wood of Edinburgh and Charles Hunter of London in 1855–1858, and improved by Luer in 1894; and the invention of the ampul by Stanislas Limousin in 1886. A committee of the Royal Medical and Chirurgical Society of London gave approval to hypodermic injections in 1867, the same year the *British Pharmacopoeia* published a monograph for the first official injection, *Injectio Morphinae Hypodermica*. No attempt was made to sterilize these solutions, but E.R. Squibb (1873) and others recommended that parenteral solutions could be preserved by the addition

of small amounts of carbolic acid, salicylic acid, chloroform, or camphor. At about the same time (1875), John Tindall developed the process of sterilization by discontinuous heating, which bears his name. Nevertheless, hypodermic routes of administration were slow to gain widespread recognition, for physicians became increasingly aware of fevers and other toxic symptoms following the use of crudely prepared injections. Ehrlich’s introduction of hypodermic injections of salvarsan for syphilis (1910) provided the strongest impetus for the development of parenteral administration, stimulating a series of rapid advancements in technique. In 1911, Martindale and Wynn discussed the pharmaceutical manipulation of salvarsan, emphasizing sterilization and aseptic techniques. That same year, Hort and Penfold applied the term *pyrogens* to describe substances that cause a febrile reaction upon injection. They found that distilled water sealed in sterile containers gave rise to toxic symptoms, whereas freshly distilled water caused no reaction; later that same year, Wechsellmann showed that febrile reactions could be eliminated if solutions were made from sterile distilled water. Seibert confirmed these findings in 1923, noting that poorly constructed stills could produce pyrogenic distilled water. In 1930, Rademaker formulated a rigid set of aseptic precautions and rules, governing the preparation of parenteral fluids, which are still valid today, and setting the stage for modern intravenous medicines. Injections are also known as parenterals (4, 5, 24, 32–33).

Insessia: Insessia refers to a vapor bath, usually administered by having the patient sit on a perforated chair, beneath which is placed a large container filled with hot water or a hot decoction of a plant drug (20).

Insufflatio: See *Insufflations*.

Insufflations: Insufflations are powders used for blowing into the nose, preferably by means of one of the various kinds of powder blowers or insufflators made for the purpose. They may also be applied directly in the way in which snuff is usually taken. Also, a snuff. The term comes from the Latin *insufflare* meaning “to breath into” or “to blow into” (2, 5).

Inunctions: Inunctions are ointments applied with friction, intended for local application and quick absorption. The term was formerly applied to preparations consisting of wool fat in which mercury or other medicinal agents were incorporated. A Compound Menthol Inunction (retitled Compound Menthol Ointment in 1936)

remained official in the *National Formulary* until 1960 (5, 24).

Inunctum: See *Inunctions*.

Irrigating solutions: See *Solutions, irrigating*.

Irrigatio: See *Solutions, irrigating*.

Jellies: See *Gels*.

Juices: Juices are liquids obtained by expression from the fresh parts of plants. The *British Pharmaceutical Codex* (1949) contained monographs for the juices of garlic, lemon, and taraxacum. In the United States, Cherry Juice remained official through the 16th edition of the *National Formulary* (1985) as a flavoring agent (4).

Juices, inspissated: Extracts prepared from the expressed juices of plants (see *Extracts*).

Juleps: A julep is a sweet drink, usually a demulcent, acidulous, or mucilaginous mixture. Much more popular in Europe than in the United States, a typical julep of the late nineteenth century (*mistura gummosa*) contained 10 parts acacia triturated with 30 parts syrup of acacia, 100 parts water, and 10 parts orange flower water (3, 20).

Konseals: Konseals is a trade name for the brand of cachets and cachet apparatus manufactured by the J.M. Grosvenor Company of Boston about 1885, originally introduced as "Morstadt's cachets" by Karl Morstadt of Prague (see *Cachets*) (5).

Lamella: See *Lamels*.

Lamels: Lamels are small disks, about 3 mm in diameter, cut or stamped from thin films of glycerinated gelatin, containing definite quantities of various medicaments used in ophthalmology. Lamels, or eye disks, are applied with a camel's-hair brush to the inner surface of the lower eyelid, where they are immediately dissolved in the lachrymal fluid. Four lamels were official in the *British Pharmacopoeia* until 1953 (24).

Lavatio: See *Washes, mouth*.

Ligamentum: See *Bandages*.

Linctus: A linctus is a thick viscid liquid that must be licked from a spoon or licorice stick, from the Latin *lingere*, "to lick" (see *Lohochs*) (5).

Liniments: Liniments are external preparations of a consistency thicker than water, but thinner than ointments, usually applied to the skin with a gentle rubbing of the hands. Liniments are among the oldest of dosage forms, along with related forms, such as plasters and ointments. The term came to its present use about 1600. Drying liniments are preparations which dry when smeared on the skin, forming a medicated film removable by water (5, 8, 19).

Liniments, dental: Dental liniments were introduced in the *National Formulary V* (1926) through cooperation between dental and pharmaceutical authorities; these concentrated, often poisonous liniments, were designed to be rubbed into the gums (5, 19).

Liniments, drying: See *Liniments*.

Linimentum: See *Liniments*.

Linimentum: exsiccantum: Drying liniment (see *Liniments*).

Lints, antiseptic or medicated: See *Dressings, medicated*.

Lintum: Lint (See *Dressings, medicated*).

Liquor: See *Solutions*.

Litus: A litus is fluid preparation applied with a brush (see *Paints, medicinal*) (5).

Lohochs: Lohochs are thick syrupy medicines, usually used to fight a cough, to be sipped slowly or licked, sometimes called a looch. If in the latter dosage form, it is usually called a linctus (5).

Looch: See *Lohochs*.

Lotio: See *Lotions*.

Lotions: Lotions are fluid preparations, usually containing suspended insoluble material and applied externally. They are different from liniments by being aqueous, rather than oleaginous or alcoholic in nature. Lotions were official in the first *National Formulary* (1888). In the mid-nineteenth century, lotions were often applied by wetting linen and placing on the affected area (1, 20).

Lozenges: See *Troches*.

Magisteries: Certain precipitates from saline solutions bore this title, but it was usually applied to secret remedies (20).

*Magma*s: In modern pharmacy, the term magma means an aqueous preparation containing precipitated inorganic material in a fine state of subdivision. *Magma Bismuthi* and *Magma Magnesia*e (milk of magnesia) were the first official magmas in the *United States Pharmacopeia IX* (1916). In the nineteenth century and previous eras, this term referred to the residue obtained after expressing organic substances to extract their fluid parts, usually referred to as a marc (19, 20).

Massa: See *Masses*.

Masses: Masses are plastic, semisolid pharmaceutical preparations composed of active medicinal substances combined with a diluent or filler and an excipient, capable of being shaped into pills with little or no further treatment. The three essential requirements of a pill mass are: adhesiveness (the mass must be sufficiently adhesive to retain its shape and yet be soft enough to be worked by the fingers or suitable apparatus into the desired form); firmness (the mass must possess sufficient firmness to permit the pills to retain their shape); and plasticity (a natural result of the proper degree of adhesiveness and firmness). Two masses appear to have survived the changes in modern medicine: Mass of Mercury (or Blue Mass), a cholagogic preparation last official in the *National Formulary IX* (1950), and Ferrous Carbonate Mass (or Vallet's Mass), a hematinic last official in the *National Formulary X* (1955) (4, 5, 24).

Medicated cottons: See *Dressings, medicated*.

Medicated dressings: See *Dressings, medicated*.

Medicated gauzes: See *Dressings, medicated*.

Medicated oils: See *Oils*.

Medicated paints: See *Paints, medicated*.

Medicated papers: See *Papers, medicated*.

Medicated pencils: See *Pencils, medicated*.

Mel: See *Honeys*.

Mellita: See *Honeys*.

Milks: Historically, the term *milk* has been applied generally to any liquid that possesses the outward appearance of milk, such as milk of magnesia. Legend holds that the class of beauty preparations called toilet milks may have arisen from Cleopatra and her milk baths. The modern milks are oil-in-water emulsions, named for their appearance and use as additives to baths. Moreover, actual milk was used and modified, especially with the addition of malt, as a medicinal beverage. Fermented Milk, or kumyss, is fresh cow's milk, to which sugar and yeast are added for fermentation. Fermented milk was official in the 3rd through the 5th edition of the *National Formulary* (1906–1926). Humanized Milk was a combination of cow's milk and fresh cream, plus Humanizing Milk Powder, which contained a small amount of Compound Pancreatic Powder and lactose, made official in *National Formulary III* (1906) (7, 34).

Mistura: See *Mixtures*.

Mixtures: Mixtures are aqueous preparations for internal use containing insoluble, nonfatty substances. They differ from emulsions in containing no fat and from liniments in being used internally. Both mixtures and emulsions were originally grouped under *Mistura* in the *United States Pharmacopoeia*; in the 7th revision (1890), emulsions were given separate recognition. Examples include Compound Mixture of Opium and Glycyrrhiza (Brown Mixture), Carminative Mixture (Dalby's Carminative), Mixture of Copaiba (Lafayette Mixture), Mixture of Copaiba and Opium (Chapman's Mixture), Mixture of Magnesia, Asafetida, and Opium (Dewees' Carminative), Oleobalsamic Mixture (Hoffman's Balsam), Compound Mixture of Opium and Chloroform (Squibb's Diarrhoea Mixture), and Expectorant Mixture (Stokes' Expectorant) (3, 5).

Mouth washes: See *Washes, mouth*.

Moxa: Moxa are cones of combustible matter used for cauterization by burning (see *Cones*). Moxibustion, the burning of moxa, was an ancient method of counter-irritation or cautery arising out of China. Small cones of combustible organic material (originally *Artimesia moxa* or common mugwort) were placed on certain areas of the skin, ignited, and allowed to burn down, leaving a blister. Moxa entered Western medicine in the seventeenth century as a treatment for gout but fell into disuse a century later along with other forms of cautery (5, 28).

Mucilages: Mucilages are viscid preparations made by dissolving or suspending gummy substances in water.

The term comes from the Latin *mucus*. The gummy substances, if natural, are carbohydrates obtained from the exudates of trees or shrubs. Gums have been used since ancient Egypt. Hippocratic works (ca. 400 B.C.) mention acacia. Mucilage of Acacia was official in the first *United States Pharmacopoeia* (1820), with Mucilage of Tragacanth becoming official in the 1st revision (1830). Both have been used as thickening agents or to prevent the creaming of emulsions (2, 19).

Mucilago: See *Mucilages*.

Mulla: See *Mulls*.

Mulls: Mulls are ointments of high fusion points, containing the desired medicinal agent, and spread on soft muslin or mull in a manner similar to that of ordinary spread plasters. The most suitable base for preparing mulls is a mixture of suet and lard, with the occasional addition of wax or lead oleate plaster. Mulls are prepared extemporaneously by tacking unsized mull over a sheet of moistened parchment paper and spreading a melted, partially cooled ointment over the mull with a broad, flat bristle brush and smoothing the surface with two warmed elastic spatulas. When cooled, the mull is covered with waxed paper and rolled into a cylinder for dispensing. Salicylic Acid Mull, Salicylated Creosote Mull, Corrosive Mercuric Chloride Mull, and Zinc Mull were last official in the *National Formulary V* (1926) (5).

Muslin, oiled: See *Silk, oiled*.

Nasal solutions: See *Solutions, nasal*.

Nebula: See *Sprays*.

Nodulus: Nodulus is an abbreviation for *nodulus uterinus*, a form of uterine bougie.

Nose drops: See *Drops*.

Oculentum: See *Ointments, ophthalmic*.

Odontalgicum: See *Toothache drops*.

Oil sugars: Mixtures of sugar with fixed and volatile oils, rendering the oils miscible to water to an certain extent, offered as a convenient mode of administering medicines to children. The *National Formulary* offered a general formula for 2% oil sugars through its 7th edition (1946) (5, 13).

Oiled silk: See *Silk, oiled*.

Oils: Any liquid that greases; i.e., leaves, when dropped on a cloth, a stain which water does not wash out; this stain makes paper translucent. If a solid substance exhibits similar properties, it is called a fat. Oils are called volatile or fixed, according to whether this stain disappears on warming or is permanent because of the nonvolatility of the oil. A few medicated oils, such as Phenolated Oil N.F. and Phosphorated Oil N.F., were briefly official (3, 31).

Oils, infused: Oleaginous preparations for external use made by macerating a drug with alcohol and ammonia water, and digesting the mixture with sesame oil at 60–70°C until the alcohol and ammonia water have evaporated. The most common, Infused Oil of Hyoscyamus, was used to make Compound Oil of Hyoscyamus. This preparation was popular in France for the treatment of earache under the name *baumé tranquille* (3).

Ointments: Semisolid preparations intended for application to the skin with or without inunction. In addition to serving as vehicles for the topical application of medicinal substances, ointments may also serve as emollients for the skin and as protectives to prevent contact of the skin surface with aqueous solutions and skin irritants. Ointments are made by fusion, incorporation, or chemical reaction. Ancient humans attributed special powers to the fats of animals and humans, and their mixtures with resins, waxes, powdered herbs, and minerals represent one of the earliest dosage forms employed. A greaseless ointment, consisting of hartshorn beaten up with incense and flour and mixed with sweet ale appears in the Ebers papyrus (1500 B.C.). The Greeks did not distinguish between liquid or semisolid preparations used for an ointment, but rather according to use or ingredients. For example, *malagma* were softening ointments, whereas *keroma* were wax ointments, the predecessor of the later cerates. Plant mucilages, balsams, and oils mixed with wax were also classified as ointments. Galen's rose water ointment (or cold cream) was an early departure (second century A.D.) from the entirely fatty type of preparation (see *Creams*). By the thirteenth century, pharmacists distinguished between *olea* or oils (liquid oily ointments), *emplastra* or plasters (masses sticking firmly to the skin), and *unguenta* or ointments (semisolid smears), a concept that remained unchanged for nearly 500 years. The first *United States Pharmacopoeia* (1820) recognized lard as the chief ingredient of the first official ointments, which were rendered to the consistency of butter by the addition of suet, wax, or spermaceti. By the middle of the nineteenth century, however, natural ointment bases began to be replaced by artificial bases, introduced with special regard

to the purposes they were to serve. Schacht introduced Glycerite of Starch in 1858, a translucent jelly prepared by heating glycerin and starch in certain proportions to a certain temperature, and W.A. Miller introduced Petrolatum in 1873 as "Cosmolin and Paraffin Ointment," both of which preparations were adopted by the *United States Pharmacopeia* in 1880. In 1885, the pharmacologist Oscar Liebreich rediscovered the therapeutic value of wool fat, the *oesypus* of the ancient Greeks, which he called lanolin; it was recognized by the *Pharmacopeia* in 1893. Later, the Russian chemist Lifschuetz discovered that the emulsification power of lanolin depended upon the free alcohols he had isolated as a group (1895–1898). In 1907, the dermatologist Paul G. Unna introduced eucerin, a new ointment base consisting of 1 part of Lifschuetz's alcohols, 20 parts of paraffin ointment, and 20 parts of water, the forerunner of the American "Aquaphor." Between 1920 and 1944, hydrogenated oils, sulfated and sulfonated hydrogenated oils, as well as stearic acid, sodium stearate, self-emulsifying glyceryl stearate mixtures, polymers of glycols (such as polyethylene glycol 4000), and esters of these glycols (such as polyethylene glycol monostearate) became important, followed by such modern bases as Plastibase, attapulgate, Veegum, guar gum, Carbopol, and the silicones, which were introduced between 1945 and 1959 (4, 5, 24).

Ointments, ophthalmic: Sterile ointments designed for application to the eyelids. Petrolatum, petrolatum-mineral oil, and petrolatum-anhydrous lanolin bases are often used in ophthalmic ointments because of their low irritating potential. Finely powdered, sterile active ingredients are aseptically incorporated into a sterile base, using sterile utensils, and dispensed in sterile ophthalmic-tipped tubes to reduce the possibility of contamination (4).

Ointments, softening: See *Cataplasms*.

Oleates: Usually liquid preparations made by dissolving alkaloids in oleic acid. Oleate of Mercury, however, is an ointment-like product of mercuric oxide in oleic acid. Oleic acid was named by the pharmacist Chevreul after olives (2, 5).

Oleinata: See *Oleates*.

Oleatum: See *Oleates*.

Oleoresina: See *Oleoresins*.

Oleoresins: Extracts of plant drugs prepared by percolation using a selective solvent (usually ether or acetone),

followed by complete removal of the solvent by evaporation. The term first arose in the 1820s (Buchner and Peschier), and the oleoresins first appeared in the *United States Pharmacopeia* of 1860 through the efforts of William Procter, Jr. (19).

Oleosacchara: See *Oil sugars*.

Oleovitamins: Preparations using fish liver oil, fish liver oil diluted with an edible vegetable oil, or a solution of vitamin concentrate in fish liver oil or in an edible vegetable oil. Oleovitamins were created during World War II to fill a therapeutic gap created by the interruption in cod liver oil supplies. The class became official in the second supplement to the *United States Pharmacopeia XI* (1942) as a source of vitamins A and D (31).

Oleum: See *Oils*.

Oleum infusum: See *Oils, infused*.

Ophthalmic ointments: See *Ointments, ophthalmic*.

Ophthalmic solutions: See *Solutions, ophthalmic*.

Orbicules: Spherical globules of sugar (see *Pills*) (5).

Oxymels: Acid-honey preparations containing acetic acid or vinegar (see *Honeyes*) (4).

Paints, medicinal: Liquid medicinal preparations possessing antiseptic, caustic, soothing, or stimulating properties, usually applied by means of a brush. Paints intended to remain in contact with a specified surface are usually prepared with collodion, glycerin, glycerin and water, egg albumin in alcohol, or gutta percha. Paints intended to be absorbed are prepared with oleic acid or fatty oils. Caustic substances are usually applied dissolved in distilled water, alcohol, or ethereal vehicles, whereas resinous substances, such as benzoin, storax, tolu balsam, or sandarac dissolved in ether, are employed as bases for medicated varnishes, and used for application to the skin and raw mucous surfaces (5).

Papers, medicated: Preparations intended primarily for external application, either by saturating paper with medicinal substances or by applying the latter to the surface of the paper by the addition of some adhesive liquid. Potassium Nitrate Paper remained official in the *National Formulary* through its 5th edition (1926), but the most widely used paper is Mustard Paper, commonly

called mustard plaster, a mixture of powdered black mustard and a solution of rubber spread on paper, cotton cloth, or other fabric, which remained official in the *National Formulary* through its eleventh edition (1960). Mustard poultices or cataplasms were formerly called sinapisms, after the botanical name for black mustard, *Sinapis nigra*, and were described in the *United States Dispensatory* (1836) as

Powerfully rubefacient... usually becoming insupportably painful in less than an hour... . As a general rule, the poultice should be removed when the patient complains much of the pain; and in cases of insensibility should not, unless greatly diluted, be allowed to remain longer than one, or at most two hours, as violent inflammation, followed by obstinate ulceration, is apt to occur.

Home-made mustard plasters (equal parts of mustard and flour, moistened with tepid water to form a paste and applied to the skin in a muslin bag) still play a role in folk medicine (5, 13, 24).

Papers, powder: See *Powders, divided*.

Papers, waxed: Parchment-like paper treated with melted wax or paraffin used largely as an economical substitute for more expensive protective dressings (see *Dressings, protective*) (5).

Parenterals: See *Injections*.

Parogenum: See *Petroxolins*.

Parvula: See *Parvules*.

Parvules: Small sugar-coated pills, of 0.06 g or less, sometimes incorrectly called granules. (also see *Granules*) (4, 5).

Pasta: See *Pastes*.

Pasta dermatologica: Dermatologic pastes (see *Pastes*).

Pastes: Ointment-like mixtures of starch, dextrin, zinc oxide, sulfur, calcium carbonate, or other medicinal substances made into a smooth paste with glycerin, soft soap, petrolatum, lard, or other fats, and medicated with antiseptic or astringent agents, designed for external use. Early pastes, such as *Pasta Glycyrrhizae* and *Pasta Althaeae*, were internal preparations, most of which were of gum-like consistency. The modern pastes were introduced by the noted dermatologists Paul G. Unna

and Oskar Lassar around 1900. Dermatologic Pastes normally contain a higher proportion of powdered material than that included in ointments and are less greasy but more absorptive than other preparations for external application. The *British Pharmaceutical Codex* groups Witch Hazel Cream, Vanishing Cream, Tannic Acid Jelly, Catheter Lubricant, and a wide assortment of “medicated preparations for external application, employed principally as antiseptic, caustic, cooling, protective or soothing dressings” under the title “Pastes.” Pastes entered the *National Formulary III* in 1906 (4, 5, 24).

Pastes, dermatologic: See *Pastes*.

Pastilles: A form of lozenge, particularly those which are chocolate flavored (see *Lozenges*); also, combustible cones of aromatic drugs used for fumigation (see *Cones*). The term came into English usage around 1650 from the French *pastille*, which was derived from the Latin *pastillus*, meaning “little loaf” (2, 5).

Pastillus: See *Pastilles* and *Cones*.

Pearls: Round or oval capsules made by enclosing liquids, solids, or tablets in a shell of glycerogelatin material. Pearls are less elastic than soft capsules and contain no air space, the glycerogelatin shell being completely filled with the medicinal substance. Pharmacists made pearls extemporaneously by laying a softened sheet of glycerogelatin over a warmed molding plate containing a specified number of semicircular (or other shaped) depressions. The sheet was covered with a measured quantity of medicinal liquid, and the liquid with a second sheet of glycerogelatin to exclude air. The whole assembly was covered with a matching molding plate, and compressed with a mechanical press to form the pearls, an exacting and time-consuming process requiring special apparatus. This process has been superseded in industry by a continuous automated process in which a liquid is injected between two ribbons of gelatin while passing between revolving dies (also see *Capsules, soft*) (4, 5).

Pelleta: See *Pellets*.

Pellets: Small spheres of sucrose saturated with an alcoholic tincture, primarily used in homeopathic medicine. Pellets are made in different sizes, designated according to the diameter of ten pellets measured in millimeters. *Remington's Practice of Pharmacy* (1926) states that pellets “should be made of the purest materials,

should be perfectly white and odorless and able to withstand all the tests prescribed for sucrose or cane sugar” (also see *Globules*) (5, 24).

Pencils, antiseptic: See *Pencils, medicated*.

Pencils, astringent: (See *Pencils, medicated*).

Pencils, caustic: (See *Pencils, medicated*).

Pencils, medicated: Cylinders used in dermatologic practice to apply medicinal agents directly to the skin. The medicinal agent is incorporated into a paste consisting of starch, dextrin, tragacanth, and sucrose with sufficient water to form a plastic mass, which is rolled into cylinders about 5 mm in diameter, cut into sections about 5 cm long, dried on parchment paper at room temperature, and wrapped in tinfoil. Medicated pencils intended as a caustic application, such as sticks of silver nitrate, are sometimes referred to as escharotica. Salicylic Acid Pencils, the last official medicated pencils, appeared in the *National Formulary V* (1926); also known as Antiseptic, Astringent, Caustic, Salve, or Styptic Pencils (5).

Pencils, salve: See *Pencils, medicated*.

Pencils, styptic: See *Pencils, medicated*.

Perles: See *Pearls*.

Pessaries: Medicated vaginal suppositories, globular or oviform in shape, weighing between 4 g (if made from oil of theobroma or cocoa butter) and 10 g (if made from glycerated gelatin). The term derives from a Greek word describing the small stones used for playing the game of draughts (5, 35).

Pessarium: See *Pessaries*.

Pessum: See *Pessaries*.

Petroxolins: Fluid preparations for external use with a base of liquid petrolatum and ammonium oleate. The preparations became official in the 6th edition of the *National Formulary* (1936) (3).

Pigmentum: See *Paints, medicinal*.

Pill coatings: See *Coatings, pill*.

Pills: Small, solid masses of a globular, ovoid, or lenticular shape intended for oral administration. Pills are

prepared by incorporating medicinal agents with other materials to form a cohesive, plastic mass, which is divided into the requisite number of portions, each of which is formed into the desired shape. Pills usually range in weight from 0.10 to 0.30 g. Exceptionally large pills of 0.60 g or more are referred to as boluses; very small sugar-coated pills of 0.06 g or less are known as parvules or granules; pellets, globules, or orbicules are small spheres of sugar saturated with an alcoholic tincture, largely used in homeopathic medicine. When the pill came into use in ancient Mesopotamia and Egypt, it offered for the first time a definite dose corresponding with a desired therapeutic action. The Greeks named the little balls of medicine *katapotia* (“something to be swallowed”), later Latinized to *catapotium*; by the first century A.D., the term *pilula* came into use in Rome. Pills persisted as a major dosage form for a remarkably long period of time. For example, over half of the prescriptions dispensed at a Charlestown, Massachusetts, pharmacy during the years 1872–1875 were for pills. Moreover, certain combinations of drugs persisted for thousands of years in pill form. The Pills of Rufus, for example, were originally a *hiera* (bitter powder) made into pill form by the Arabs and popularized by Avicenna (980–1033); a modern version, Pills of Aloe and Mastic, were last official in the 8th revision of the *United States Pharmacopeia* (1905) (4, 5, 36–37).

Pills, compressed: See *Tablets*.

Pills, enteric-coated: See *Enteric-coated doses*.

Pilula: See *Pills*.

Pilula comprimata: Compressed pills (see *Pills*).

Pilula enterica: Enteric-coated pills (see *Pills*).

Pilules: See *Pellets*.

Plasma: Nonfatty unctuous preparations (5).

Plasters: Substances intended for external application, made of such materials and of such consistency as to adhere to the skin. Adhesive plasters afford protection and mechanical support, whereas medicated plasters furnish an occlusive and macerating action, bringing the medication into close contact with the skin; when spread on perforated cloth, the product is called a porous plaster. Plasters are among the most ancient of all pharmaceuticals. Primitive humans may have used plasters of mud and leaves to help heal wounds or relieve pain. The Ebers papyrus (1500 B.C.)

describes several plasters and poultices for treating burns, and the Greeks assigned a special place within their temples where plasters were prepared. Indeed, the word plaster is derived from the Greek *emplastron* meaning “to smear on” or “to mold on.” The famous diachylon plaster, made from oil, litharge, and certain plant juices was compiled by Menecrates, physician of the Emperor Tiberius about 39 A.D. and passed on in verse form to Claudius Galen (131–201), who developed a number of practical formulas for plasters and procedures for their preparation which endured for centuries. A modern version of diachylon plaster survived as Lead Oleate Plaster (or Lead Plaster) in the *United States Pharmacopeia* and later in the *National Formulary* through its 8th edition (1946). Originally, plasters were spread directly on the affected part of the body; by the sixteenth century, plaster material was being spread on linen or leather or dipped. In 1514, Giovanni da Vigo popularized spread plasters called sparadraps or spasadraps; in 1691, William Salmon described dipped cerecloths in his *Pharmacopoeia Londonensis*. Plasters were spread with the aid of an offset spatula or plaster iron heated by means of a spirit lamp, an arduous and time-consuming process which exhausted the patience of pharmacists who struggled trying to keep the refractory plaster masses warm and malleable. Although Elisha Perkins of Baltimore is credited with obtaining the first American patent for a manufactured plaster (1830), John C. De La Cour of Camden, New Jersey, is generally credited as among the earliest producers of machine-spread adhesive plasters (1836), one of the first commercially prepared dosage forms manufactured in the United States. In 1852, an English apothecary named Mather patented a method of spreading plasters on leather by the use of heated rollers, producing a thinner and more uniform product, leading Edward Parrish to observe in his classic text, *American Pharmacy* (1856), that “the spreading of plasters which was formerly an important part of the business of the apothecary has now ... been monopolized by manufacturers who bring machinery to their aid.” The only plaster which still finds significant use today is Salicylic Acid Plaster, *United States Pharmacopeia*—the common corn plaster (also see *Plasters, adhesive*, and *Plasters, porous*) (4, 5, 15, 24, 38).

Plasters, adhesive: A mixture of rubber, resins, and waxes, with a filler of absorbent powder, such as zinc oxide, orris root, or starch, mechanically mixed and spread on cotton cloth. Early adhesive plasters were composed of resin and litharge or diachylon spread on calico, muslin, or linen. In 1843, B.C. Rowland of Liverpool, England, reported on an “India Rubber Court Plaster” made by

dissolving India rubber in naphtha or turpentine and spreading the liquefied rubber on silk or satin. Two years later, Horace Day and William Shecut of New York City patented a combination of India rubber and gums as a plaster mass. In 1852, Benjamin Nickels of Surrey, England, patented an “elastic plaster” combining adhesive material on an elastic fiber. In 1863, Joshua Melvin of Lowell, Massachusetts, patented the manufacture of adhesive plaster in roll or cylindrical form. By the early twentieth century, two types of rubber-based adhesive plasters emerged: surgeons’ adhesive plaster, a plain yellow-colored mass, and zinc oxide adhesive plaster, a white mass containing zinc oxide. Modern adhesive plasters, consisting of vinyl resin, plasticizers, and other chemical additives have an excellent ability to remain adhered under severe conditions of moisture and heat, and rarely cause skin irritation. Adhesive plaster remained official through the 19th revision of the *United States Pharmacopeia* (1975) (also see *Plasters* and *Plasters, porous*) (5, 15, 24).

Plasters, Blister: Plasters designed to produce inflammation, blisters, or issues (running sores). Many blistering agents were used to prepare blister plasters, but the potent and powerful cantharides (or Spanish flies), was the most widely applied. It was used internally by the ancients, who were well aware that it produced hematuria even when applied externally. Aretaeus introduced an external preparation of cantharides as a blistering agent in the second century to the shaved head to relieve headache. This treatment was also used for epilepsy and vertigo, and persisted through the centuries, but only after the patient had been given milk to drink for 3 days to protect the bladder from injury. “In many constitutions the strangury will ensue, especially where the discharge of serous juice is too great,” an English textbook on materia medica advised in 1730. “But, however it be, such applications are necessary when a patient proves delirious, as frequently happens in high fevers.” A century later, the *United States Dispensatory* (1836), in discussing the use of Cerate of Cantharides, “the common blistering plaster of the shops,” remarked that

When the full operation of the flies is desirable, and the object is to produce a permanent effect, the application should be continued for twelve hours... . It should then be removed, and followed by a bread and milk poultice, or some other emollient dressing, under which the cuticle rises, and a full blister is usually produced. By this management the patient will escape strangury, and the blister will very quickly heal after the discharge of the serum.

Elisha Perkins of Baltimore obtained a patent in 1830 for an apparatus to prepare blister plasters. George W. Carpenter of Philadelphia sold and recommended Perkin's blister cloth in 1831 as "a very convenient article for the country physician, being ready spread for immediate use." *Ceratum Cantharides* was official in the *United States Pharmacopeia* and, later, in the *National Formulary* until 1950 (13, 15, 28).

Plasters, porous: Adhesive plasters spread on perforated cloth. Sir William Butts, royal physician to Henry VIII, devised a "spasmodrap or dypped plaster" which was to be poked "full of smalle hoolys." In 1845, Horace Day and William Shecut of New York City patented a rubber-based "porous plaster" rendered full of minute holes to "allow the free escape of the perspiration." In 1854, Somerville Scott Alison of London patented a porous or "perforated Lambskin... prepared according to the process called chamois curing." The porosity is considered a mechanical advantage in that it prevents the plaster from slipping from the point of application, each opening serving as a stop. Porous plasters are also far more comfortable than the nonporous variety, which they have superseded (also see *Plasters* and *Plasters, adhesive*) (5, 15).

Politzer plugs: Greased pellets of cotton about the size of a coriander seed with a thread attached, for insertion into the ear as a protective. The pellets were named after Adam Politzer (1835-1920), an Austrian otologist (1, 2).

Pomatum: Fats saturated with odorous principles (5).

Potio: See *Draughts*.

Potions: See *Draughts*.

Potus: See *Draughts*.

Poultices: Originally spelled "pultes" in sixteenth-century England, the term came from the Latin *puls* or *pultes* meaning "a pottage of meal" (also see *Cataplasms*) (2).

Powder papers: See *Papers, divided*.

Powders: Intimate mixtures of dry, powdered medicinal substances reduced to a fine powder by the processes of comminution and trituration. Bulk powders are divided into two categories: simple, consisting of one substance, and compound, consisting of two or more powders mixed together. One of the most ancient compound powders was *hiera picra* ("sacred bitters"), a mixture of aloe and canella introduced about 500 B.C. as a laxative, the prototype of a

large number of bitter powders containing aloe as the principal ingredient and bearing the general title *Hiera*. This powder was listed in various pharmacopoeias and was last recognized in the 4th edition of the *National Formulary* (official until 1926). Powders were designed originally as a convenient mode of administering hard vegetable drugs such as roots, barks, and woods; powders were also found to be convenient for the dispensing of insoluble chemical compounds such as calomel, bismuth salts, mercury, and chalk. Famous compound powders of the past include: Compound Powder of Glycyrrhiza, a variant of Compound Senna Powder recognized by the first *London Pharmacopoeia* (1618); Powder of Ipecac and Opium, or Dover's Powders, introduced by the English physician Thomas Dover as *Pulvis Diaphoreticus* in the early eighteenth century; Aromatic Powder of Chalk, a simplified version of a complex confection devised by Sir Walter Raleigh during his imprisonment and introduced into the *London Pharmacopoeia* of 1721 as *Confectio Raleighana*; and Antimonial Powder, patented in 1747 as Dr. James's Fever Powder. The *United States Dispensatory* (1836) noted that "the form of powder is convenient for the exhibition of substances which are not given in very large doses, are not very disagreeable to the taste, have no corrosive property, and do not deliquesce rapidly on exposure." Today, drugs not available in capsule or tablet form can still be conveniently administered in powdered form by placing them on the back of the tongue and swallowing them with water. Flavored powders are particularly useful for children who might have difficulty swallowing a tablet or capsule (also see *Powders, divided*) (4, 5, 13, 24).

Powders, divided: Intimate mixtures of dry, powdered medicinal substances intended for oral administration, divided into single doses, each of which is folded into a small sheet of glassine paper. One of the oldest of dosage forms, divided powders have largely been replaced by capsules or tablets. Nevertheless, the preparation of powders permits the drugs to be reduced to a very fine state of subdivision, a physical condition which frequently intensifies their therapeutic activity, a factor in increasing the efficacy of homeopathic triturations, calomel and sodium bicarbonate mixtures, and Dover's Powder (Powder of Ipecac and Opium). Divided powders also furnish a convenient means for administering drugs that are not excessively bitter, nauseous, or otherwise offensive to the taste. One of the most durable divided powders is Seidlitz Powders, a saline cathartic originated and patented by Thomas Savory in 1815. Savory claimed that the powders owed their value to the mineral properties of the Seidlitz

spring in Germany, which contains magnesium sulfate. The powders consist of sodium bicarbonate (wrapped in blue paper) and tartaric acid and potassium and sodium tartrate (wrapped in white paper), each of which are dissolved separately in water and then mixed. The formula was exposed in a book of recipes for patent medicines published by the Philadelphia College of Pharmacy in 1824, and remained official as Compound Effervescent Powders in the *United States Pharmacopeia*, and later in the *National Formulary* through its 12th edition (1965); also known as *Powder papers* (5).

Precipitates: Drugs prepared by separating particles from a previously clear liquid by physical or chemical means. Precipitation usually occurs when a hot saturated solution of an amorphous substance is allowed to cool or when a liquid in which the dissolved substance is insoluble is added to its solution. Pharmacists formerly used the process of precipitation as a convenient method of obtaining solid substances in fine particles (precipitated calcium carbonate), to purify solids (precipitated calcium phosphate), or to prepare mercury salts. White precipitate (ammoniated mercury) was first described by Beguin in 1632, a soluble double chloride of mercury and ammonium known to the alchemists as *sal alembroth* and *sal sapientiae*, respectively. Red precipitate (red mercuric oxide) was known to alchemists as *hydragyrum precipitatum per se* or “precipitate per se”; yellow precipitate is a synonym for yellow mercuric oxide (5, 24).

Preserves: See *Conserves*.

Protective dressings: See *Dressings, protective*.

Pulvis: See *Powders*.

Quiddonies: Preparations with a vehicle of thick, quince-flavored syrup (also see *Syrups*) (39).

Resina: See *Resins*.

Resins: Solid preparations consisting chiefly of the resinous principles from vegetable bodies. The officially prepared resins differ from alcoholic extracts in that the latter contain all of the alcohol-soluble principles in the drugs, whereas the resins contain only the alcohol-soluble principles that are insoluble in water. The term probably arose from the Greek *rheos*, “to flow,” referring perhaps to the flow of pine resin commonly observed (2, 5).

Rotula: Globules or orbicules (see *Pills*) (5).

Rubificients: Local remedies which produce redness and inflammation of the skin. The word comes from two Latin words: *ruber*, meaning “red,” and *facio*, meaning “to make” (2, 13).

Saccharures: Preparations made by saturating sucrose with a tincture, drying it, and grinding the mixture to a powder (5).

Saccelli amylacea: See *Wafer envelopes*.

Sacculi: Abbreviation for *sacculi medicinales*, or “bags of drugs” (20).

Sal: See *Salts*.

Sal effervescens: See *Salts, effervescent*.

Sal factitium: See *Salts, artificial*.

Salts: Compounds formed by the union of acids and bases, by the action of alkalies upon metals, or by the direct union of elements. The term is often incorporated in the common name of salts used as pharmaceuticals: bitter salts, epsom salt, or Seidlitz salt (magnesium sulfate), preparing salt (sodium stannate), Preston’s salts (ammonium chloride), Rochelle salt or Seignette’s salt (potassium and ammonium tartrate), salt of Mars (ferrous sulfate), salt of Saturn (lead acetate), salt of tartar (potassium carbonate), salt of tin (stannous chloride), salt of wisdom (mercury bichloride and ammonium chloride), sore-throat salt (fused potassium nitrate), vinegar salts (calcium acetate), and vomiting salt (zinc sulfate). The term is also applied to some acids, such as salt of lemon or sour salt (citric acid), salt of sorrel (oxalic acid), and spirit of salt (muriatic acid) (5, 13).

Salts, artificial: A mixture of the more important chemical salts naturally present in several of the well-known mineral springs of Europe. “These are properly labeled artificial,” notes *Remington’s Practice of Pharmacy* (1926), “and if used to prepare effervescent salts or mineral waters they should be sold only as an imitation of the genuine” (5).

Salts, effervescent: Granular effervescent salts were formerly made by mixing dry powders with dry tartaric acid and sodium bicarbonate and moistening the mixture with strong alcohol. The pasty mass was passed through a sieve, and the granules dried quickly in a hot room, sifted, and filled into bottles, which were hermetically sealed to prevent the access of moisture. This method was greatly

improved upon by mixing the powders in a flat enameled dish and heating in an oven to about 100°C or by heating the mixture in a deep jacketed kettle or in a pill-coating pan, heated, as it revolves, by a gas flame. When the mixture becomes moist, it is manipulated with a wooden spatula to make it uniform in consistency, and rubbed through a coarse tinned iron sieve; the granules obtained are dried slowly at a low heat in an oven (5).

Salts, smelling: Ammonia-based preparations used as a restorative in “hysterical syncope” (fainting). Dry smelling salts (or vinaigrettes) are composed of ammonium chloride and potassium carbonate, perfumed with lavender; liquid smelling salts are composed of ammonium carbonate dissolved in stronger ammonia water and alcohol, and perfumed with oils; solidified smelling salts are similar preparations solidified with stearic acid (5).

Salve pencils: See *Pencils, medicated*.

Salves: This term probably arose from the Anglo-Saxon *sealf* or the German *salbe*, both meaning “ointment” (see *Ointments*) (2).

Scutum: Abbreviation for *scutum stomachicum*, a large plaster, applied to the breast or stomach (20).

Semicupia: A half-bath, used interchangeably with *Insessia* (20).

Sericum oleatum: See *Silk, oiled*.

Serums: Serum therapy came into prominence in the 1890s when Emil von Behring (1854–1917) extended Pasteur’s theory of attenuated viruses. Behring demonstrated that the serum of animals immunized against attenuated diphtheria toxins can be used as a preventive or therapeutic inoculation against diphtheria in other animals through a specific neutralization of the toxin of the disease. In 1894, Behring began to produce his new antitoxic serum on a grand scale; it soon became recognized as the specific treatment for diphtheria. Antisera act by combining with the toxin in the blood of the patient, rendering it inert. Scarlet fever, tetanus, erysipelas, botulism, and gas gangrene have been successfully treated by antitoxic serums prepared in this manner. Antibacterial serum is produced by injection of an animal with successive doses of bacteria. The immune substances thus formed act by enhancing phagocytosis, destroying the bacteria. Pneumonia, streptococcic infection, and spinal meningitis have been aided by the use of this type of serum. Mixed serum

contains both antitoxic and antibacterial immune bodies; the serum used to treat scarlet fever is of this type (3, 40).

Shampoos: A wash for the hair or soap for hair washing. The term comes from the Hindustani word *tshampa*, meaning “to squeeze” or “to press,” probably associated with hot oriental baths (2).

Silk, oiled: A thin, very soft, and pliable protective dressing made of fine silk, coated with a flexible linseed-oil varnish. Oiled Silk is available in semitransparent or opaque form, made by the addition of talc or starch in the final coating. Oiled Muslin or Oiled Cambric is similar to oiled silk, except that the basic fabric is of glazed cotton; it is thicker and heavier and consequently less pliable than oiled silk (see *Dressings, protective*) (5).

Sinapismus: See *Plasters, blister*.

Sindon oleata: Oiled muslin or Oiled cambric (see *Silk, oiled*).

Snuffs: See *Insufflations*.

Soaps: A class of chemical substances which are metal salts of fatty acids. Pliny (first century A.D) records that the ancient Romans learned the preparation of soap from Nordic tribes, who used a pomade prepared from goat fat and the calcined ashes of beechwood. *Sapo*, the Latin word for soap, is derived from the Nordic *sepe*. The chemistry of soaps was elucidated in the early nineteenth century by French chemist M.E. Chevreul (1786–1889). Soaps may be divided into two classes: soluble soaps (or detergent or cleansing soaps), which are compounds of fatty acids with alkali metals, particularly sodium and potassium; and insoluble soaps, which are compounds of fatty acids and metals of any other group, such as Lead Oleate Plaster or Lime Liniment, a calcium soap of linseed oil. Soluble soaps include Hard Soap (or Castile Soap), prepared from olive oil and sodium hydroxide, official through the 11th edition of the *National Formulary* (1960), and Soft Soap (or Green Soap), prepared from linseed oil, glycerin, and dekanormal solutions of sodium and potassium hydroxide; the latter continues to hold official status (4, 5).

Soft capsules: See *Capsules, soft*.

Solutio: Dental preparations official only in the 5th edition of the *National Formulary* (1926), consisting of a solution of a resinous material dissolved in chloroform (3).

Solution tablets: See *Tablets, solution*.

Solutions: Liquid preparations that contain one or more substances dissolved in a solvent and, by reason of their ingredients or method of preparation, do not fall into some other category of preparation. From the seventeenth century on, the term *liquor* denoted liquid solutions. By the early twentieth century, liquor usually referred to aqueous solutions of nonvolatile substances. For example, Solution of Magnesium Citrate, *United States Pharmacopeia*, had the Latin title *Liquor Magnesii Citratis*. Beginning with the *United States Pharmacopeia XVI* and the *National Formulary XI* (1960), the term liquor was dropped and solutions were listed by their active ingredient or ingredients (19).

Solutions, irrigating: A preparation to be applied continuously by means of a special device for the purpose, as in the treatment of wounds with Dakin's solution (5).

Solutions, nasal: Solutions of drugs for instilling in the nose rather than spraying are generally a modern development. The first nasal solutions were formulated with menthol and thymol dissolved in light mineral oil. Later isotonic aqueous solutions were designed as drops (3).

Solutions, ophthalmic: Originally called collyria, ophthalmic solutions arose from the eye washes of the ancient world. Early preparations were not the sterile, buffered solutions of today. The term collyrium comes from the Greek *kollurion*, which Hippocrates used to designate fatty suppositories for gynecological purposes. They were formed into sticks, from which a paste was made with a liquid. Eventually, more liquid was added and the paste thinned to a lotion. This lotion was used as an eye wash, and term came to be used exclusively for this type of preparation. Remington's formula for a collyrium of 260 mg (4 grains) of sodium borate in 30 mL (1 oz) of camphor water was a standard from 1886 into the mid-twentieth century (2, 41).

Sovella: See *Tablets, solution*.

Spasmadraps: Pieces of linen or other cloth dipped in or spread with a medicinal plaster, popularized in 1514 by Giovanni da Vigo (1460–1525), physician to Pope Julius II. From the Latin *spasma* meaning “healing powder” and the French *drap* meaning “cloth.” Also known as sparadraps or cerecloths (see *Plasters*) (15).

Species: See *Teas*.

Spirits: Solutions of volatile substances (usually volatile oils) in alcohol. Some editions of the *National Formulary*

stated that “spirits of volatile oils” contained 6.5% of the volatile oil, but that figure was later rejected as too low. Although used internally, several spirits were used medicinally by inhalation or as flavorings (4, 31).

Spiritus: See *Spirits*.

Sprays: Medicated liquids prepared for dispersal by atomizers or nebulizers, usually on external surface or mucous membranes of the respiratory tract. In the *United States Pharmacopoeia*, sprays were called *inhalatio*; the *National Formulary* referred to them as *nebulae*. Sprays of the early twentieth century were formulated with aromatics dissolved in light mineral oil. As injuries from inhaled oils became apparent, especially among children, these sprays were displaced by buffered aqueous solutions (1, 31).

Starch capsules: See *Cachets*.

Steam: See *Vapors*.

Steatina: A salve mull (see *Mulls*) (5).

Stilus dissolubilis: Dissolving pencils (see *Pencils, medicated*). Pencils containing a caustic or an astringent (5).

Stilus medicatus: See *Pencils, medicated*.

Stilus unguentis: Salve pencils, cooling, antiseptic, or astringent (see *Pencils, medicated*) (5).

Stupa: See *Stypes*.

Stypes: Cloths wrung out of hot water and sprinkled with a counterirritant (2).

Styptic pencils: See *Pencils, medicated*.

Succus: See *Juices*.

Succus spissatus: Condensed juice (see *Extracts*).

Sugar plums: See *Condita*.

Suppositories: Conical or ovoid medicated solids intended for insertion into one of the several orifices of the body, excluding the mouth. Suppository use has been known as early as 2600 B.C., and was recommended in the works of Hippocrates (ca. 400 B.C.). The term derives from the Latin *suppositus*, meaning “to place under.” Premodern suppositories were made by hand using soap

or other semisolid fatty substances as the main vehicles. They were not commonly used until the seventeenth and eighteenth centuries and did not become popular until the mid-nineteenth century and the advent of cocoa butter as vehicle. In 1766, Antoine Baumé described a suppository mold which used liquefied cocoa butter. This technique was popularized in America by Alfred B. Taylor about 1852 using paper cones as molds. Metal molds were introduced about 1860, although many pharmacists continued to form suppositories by hand without heat. Cold compression of cocoa butter was made possible through the introduction of metal suppository presses about 1868, although the first popular compression mold was not introduced until 1879. After 1870, mixtures of glycerin and gelatin came to be used as vehicles for suppositories, beginning a quest for the perfect vehicle that continues to the present (2, 19, 42).

Suppositorium: See *Suppositories*.

Suspensio: See *Suspensions*.

Suspensions: Heterogeneous systems containing coarsely dispersed material that settles. A wide variety of pharmaceutical preparations have been used as suspensions, for example, White Lotion, Magma of Bismuth, and Compound Mixture of Opium and Glycyrrhiza (Brown Mixture). In addition, several official ointments are suspensions of solids in a semisolid base. A large number of suspensions are categorized as mixtures in the *United States Pharmacopeia* and the *National Formulary* (19).

Swabs: Ampuls containing Iodine Tincture, *United States Pharmacopeia*, covered with gauze or other absorbent material, and used for first-aid treatment. Iodine Swabs, later called Iodine Ampuls, were official in the *National Formulary* through its 13th edition (1970). When iodine tincture is required for first aid, the tip of the ampul is broken and the gauze absorbs the iodine and provides a means of applying it directly to the wound. Some Iodine Ampuls are in the form of fine capillary tubes, which are broken when needed and the tincture applied directly (24).

Sweetmeats: See *Condita*.

Syrups: A nearly saturated aqueous solution of sugar (usually sucrose) with or without medicinal or flavoring ingredients. Syrups are usually divided into flavored, containing a fruit or aromatic substance for a pleasant taste, and medicated, containing a drug. Simple Syrup,

United States Pharmacopeia was commonly used in the preparation of pill masses and other mixtures (3, 8, 19).

Syrupus: See *Syrups*.

Tabella: See *Tablets*.

Tablet Triturates: See *Triturates, tablet*.

Tablets: Dosage forms prepared by molding or compressing medicinal substances in dies. Tablets vary widely in shape, the most common form being discoid, and range from 0.06 to 0.60 g in weight. Jean de Renou applied the Latin word *tabella* to a special type of troche in 1608; Burroughs Wellcome & Company coined the term “tablet” in 1878 to refer to its brand of compressed pills; the term is derived from the French *tablette*, meaning “shelf” and the Latin *tabula*, meaning “board.” In 1843, the English apothecary William Brockedon patented a device for compressing medicinal agents commonly employed in pills and lozenges without the use of liquid adhesive agents; the resulting product was known as compressed pills. The Philadelphia druggist Jacob Dunton invented a similar device in 1864, marketing his own compressed pills in 1869; Joseph Remington devised a similar machine in 1875 to allow the retail druggist to “manufacture his own medication called for on prescription.” Each of these devices consisted of a compression cylinder and lower die (to hold the medicinal substance) as well as an upper die which was struck with a mallet to compress the material. More reliable compression was achieved by using the screw devices invented by Germany’s Professor Rosenthal (1874) and perfected by Austria’s Carl Engler (1907). Another advancement was the lever device introduced by Philadelphia’s Bennett L. Smedley (1879). The first rotary tablet machine was developed in 1872 by Henry Bower, an employee of the Philadelphia drug manufacturer John Wyeth; two years later, Joseph A. McFerran received a patent for the first fully automatic tablet machine (2, 4, 43).

Tabletta: See *Tablets*.

Tablets, compressed: See *Tablets*.

Tablets, dispensing: See *Tablets, solution*.

Tablets, enteric-coated: See *Enteric-coated doses*.

Tablets, hypodermic: Molded tablet triturates intended to be dissolved in water to make a solution to be injected parenterally. The usual weight of hypodermic tablets is about 0.03 g, which distinguishes them from

ordinary tablet triturates that weigh about 0.06 g. Formerly prepared extemporaneously by pharmacists, modern compressed hypodermic tablets are not intended to be sterile, although they are manufactured under strict conditions as a precaution against contamination (see *Triturates, tablet*) (4).

Tablets, molded: See *Triturates, tablet*.

Tablets, poison: Tablets of mercury bichloride in an angular, not discoid shape, blue in color, each having the word "POISON" and the skull-and-crossbones design distinctly stamped upon it. A unique one-product classification, poison tablets (or *Toxitebellae*) first became official in the *United States Pharmacopoeia IX* (1916), and two strengths remained official in the *National Formulary* through its 10th edition (1950); the larger tablets remained official through the 12th edition (1965). Diluted in a solution of 1:1000 concentration, mercury bichloride is an antiseptic used chiefly for the disinfection of inanimate objects and the unabraded skin (4, 5, 24).

Tablets, solution: Molded or compressed tablets containing large amounts of potent substances not intended for administration, but rather as a convenience in dispensing; also known as Dispensing Tablets. To lessen the risk of their being dispensed by mistake for other tablets, dispensing tablets are always of angular rather than discoid shape. They are usually scored to facilitate division into more or less accurate fractions. Also tablets to be dissolved in water for external use (4).

Teas: Coarsely powdered mixtures of dried herbs intended for medicinal teas or poultices; also known as Species. The *National Formulary* recognized an Emollient Species, used as a cataplasm; a Laxative Species (St. Germain Tea); and a Pectoral Species (Breast Tea) for a "catarrhal condition of the respiratory tract" through its 5th edition (1926). Similar teas from home-grown herbs persist as common household remedies. True tea from China was introduced to England by Christopher Borough in 1379. The English word probably comes from the Dutch *thee* (2, 5, 24).

Tinctura: See *Tinctures*.

Tinctures: Alcoholic or hydroalcoholic solutions of drugs, usually of plant origins. The term comes from the Latin *tingere*, "to dye or soak in color." Tinctures, as alcoholic solutions, entered medical practice in the thirteenth century through the efforts of Raymond Lull and Arnald of Villanova. Paracelsus (1493–1541) was a

strong advocate for tinctures; inasmuch as he was controversial, his advocacy probably discouraged their incorporation into compendia until the 1700s. In the 1800s, wine remained the prime hydroalcoholic vehicle in the United States. After the turn of the century, however, tinctures (and elixirs) displaced those wines because of their wide variation in strength. Moreover, prohibition impeded their widespread use. As galenicals declined throughout the twentieth century, tinctures lingered on as an official class, mainly as flavorings, for example, Tincture of Orange Peel. Homeopathic Tinctures are generally prepared by long maceration of freshly dried succulent plants or their parts in alcohol, the completed tincture being made to represent one part of the dry crude material in each ten parts of the completed preparation (2, 5, 19).

Tinctures, homeopathic: See *Tinctures*.

Tincture triturations, homeopathic: See *Triturations*.

Toothache drops: See *Drops, toothache*.

Toxitebella: See *Tablets, poison*.

Triturates, tablet: Small, disk-like masses of medicinal powders prepared by forcing a moistened tablet mass into a die by manual pressure and allowing them to dry and harden. The basis of tablet triturates is usually a mixture of lactose and sucrose in a 5:1 ratio, moistened with a volatile liquid such as alcohol. Tablet triturates were introduced in New York in 1878 by Dr. Robert W. Fuller as a palatable and convenient means of administering potent drugs by mouth. Fuller's original triturates consisted of triturations of metallic, mineral, and vegetable matter, mixed into a paste with alcohol or water, and molded into the desired shape. In 1882, Fuller described a perforated, hard rubber tablet triturate mold with a corresponding pegged plate, which was practically identical to those available today. Tablet triturates served the purposes of homeopathic physicians well and undoubtedly helped to further the use of homeopathic doses. Twentieth-century pharmacists also prepared hypodermic tablets (used for preparing hypodermic injections) utilizing the technique. Today, tablet triturates and hypodermic tablets are formed by compression and are termed molded tablets (4, 5, 43).

Trituratio: See *Triturations*.

Triturations: Dilutions of potent powdered drugs prepared by intimately mixing them with a suitable diluent,

usually lactose, in a definite proportion by weight, usually 10%, used as a dispensing aid. Such poisonous substances as strychnine sulfate, arsenic, mercury bichloride, and atropine are much more accurately dispensed using this technique, the pharmacist weighing a multiple of the prescribed drug in a triturated form. Homeopathic triturations were formerly prepared by triturating one part of a drug into 99 parts of lactose over a period of at least one hour; homeopathic tincture triturations were prepared by mixing 10 mL of a homeopathic "strong tincture" with 10 g of lactose and triturating the mixture gently until dry. Although such powdered triturations were being replaced by commercially prepared tablet triturates by the mid-1920s, a general formula for triturations, specifying geometric dilution, remained official in the *United States Pharmacopeia* through its 14th revision (1950) (5).

Triturations, homeopathic: See *Triturations*.

Trituraations, tincture: See *Triturations*.

Troches: Solid dosage forms in the form of small disks, cylinders, or tablets, intended to be placed in the mouth and allowed to dissolve or disintegrate slowly. The term is derived from the Greek *trochos*, meaning "round" or "circular." They were subsequently called *pastils* in French and lozenges in English. One of the earliest troches (500 B.C.) was *terra sigillata*, or sealed earth, a product composed of clay from the island of Lemnos and goat's blood, rolled and cut into disks and impressed with a seal; by the Middle Ages, a variety of troche presses were employed. In 1856, Edward Parrish described an apparatus for rolling and cutting troches consisting of a rolling-board, wooden roller, and cutting punch. During the next two decades, F.L. Slocum (1879), F.E. Harrison (1880), Wallace Procter (1894), and nearly a dozen others patented similar machines. The 4th edition of the *National Formulary* (1916) featured nine formulas for troches; by the mid-1930s, troches were being replaced by tablets: the 6th edition (1936) featured only Troches of Elm. Modern troches consist of powdered drugs bound with sugar and tragacanth or incorporated into a hard candy or glycerogelatin base (2–4).

Trochiscus: See *Troches*.

Unguenta extensa: See *Mulls*.

Unguentum: See *Ointments*.

Vapor siccus: See *Inhalations, dry*.

Vapors: Steam, plain or medicated, generated by the use of steam or boiling water or by the use of a specially constructed apparatus (5).

Vesicatories: Local remedies, the application of which produces a serous discharge beneath the skin, forming a blister. Also known as epispastics (13).

Vials: See *Ampuls*.

Vinaigrettes: See *Salts, smelling*.

Vinegars: Infusions or solutions of drugs in vinegar or acetic acid; one of the oldest methods of drug preparation. Ancients knew that vinegar was often a better solvent than water and a preservative as well. The first preparation listed in the first *United States Pharmacopeia* (1820) was *Acetum Opii*, or Vinegar of Opium. The English word derives from the French *vin*, "wine," and *aigre*, "sour" (2, 8, 19).

Vinum: See *Wines*.

Wafer capsules: See *Cachets*.

Wafer envelopes: Preformed envelopes of rice flour used to administer bitter or nauseating drugs. Developed by Johann Schmidt as *sacculi amylacei*, wafer envelopes marked an improvement of convenience over wafer sheets. Pharmacists often furnished empty wafer envelopes to their patients, who transferred doses to them from prepared powder papers (see *Wafers*) (5).

Wafers: Flat sheets of rice flour used to administer nauseating drugs. When dry, wafer sheets are nonadhesive, stiff, somewhat brittle, and slightly thicker than ordinary cardboard. Powders are administered by floating a piece of wafer sheet upon water until it becomes thoroughly softened, passing a tablespoon underneath and lifting it out, and depositing the powder in the center and folding over the corners to thoroughly enclose the powder. If water is poured into the spoon, the concealed powder can be swallowed without any disagreeable taste being perceived. Wafer sheets are made by pouring a mixture of rice flour and water upon hot greased plates or rolling it between two hot, polished, revolving cylinders (5).

Washes: Aqueous preparations designed to cleanse specific parts of the body. Examples include enemas, eye drops, mouth washes, and nasal washes. General washes made official include Alkaline Aromatic Solution N.F. and Antiseptic Solution N.F. (31).

Washes, eye: See *Solutions, ophthalmic*.

Washes, mouth: Hydroalcoholic solutions of soap flavored with essential oils for cleansing the oral cavity; they became first official in the *National Formulary V* (1926) (31).

Waters, aromatic: Saturated solutions usually of volatile oils or similar substances in distilled water. Aromatic waters such as rose water were used in antiquity. Distilled waters containing volatile oils reached their therapeutic peak in the early sixteenth century. Although their therapeutic use declined in modern times, they continued to be used as flavorings. Hamamelis water (witch hazel) has lingered on as an aftershave and astringent (19).

Wax, dental See *Drops, toothache*.

Waxed papers: See *Papers, waxed*.

Wines: Alcoholic liquids prepared from drugs by the process of solution, maceration, or percolation, differing from tinctures only in that wine is used as a solvent or menstruum instead of various strengths of alcohol; one of the oldest liquid preparations, since the alcoholic content of the wine improved its solvent characteristics in many cases. The *National Formulary IV* (1916) recognized 15 wines, but the passage of Prohibition convinced the revisors to drop red and white wine, as well as all medicated wines, from that compendium (3).

HEALTH CARE SYSTEMS: WITHIN THE UNITED STATES

Henri R. Manasse, Jr.

American Society of Health-System Pharmacists, Bethesda, Maryland, U.S.A.

INTRODUCTION

A national health care system reflects the social, political, economic, and cultural character of a nation. A nation's historical roots and dominant values shape policies and directions for the organization, quality, financing, and access to health care services. These factors determine who gets what kind of care—at which locations, for what price, and paid by whom.

The distinctive historical antecedents of American cultural and social development have shaped the present health care system. These contexts have led to a health care system that is uniquely American in character and composition. Although the issues currently facing the American health care system bear some similarity to those in other developed, industrialized nations, many of the factors are unique to the United States.

Social values, that is, the collective societal beliefs about the nature of the human being and the structure of a society, play a strong role in the development of national policies. Political and economic decisions rest in large measure on the prevailing values held in a society. Hence, if a predominant social value rests on the notion that all societal members have a right to health care, political and economic policy developments will follow suit. One way of examining these contexts is to look at a spectrum of social values.

Donabedian (1) has proposed that such a spectrum might be considered from two polar positions: libertarianism versus egalitarianism. Dougherty (2) adds the dimensions of utilitarianism and contractarianism. The essence of these taxonomies of social values is that they characterize specific sets of beliefs and values held by a wide array of individuals.

Libertarian philosophical thought places major emphasis on personal achievement and freedom from political intervention. It holds that individuals should be free to exert their rational capacity to evaluate and determine what is good for them. They can then further act on these determinations for themselves from their own personal, fiscal, physical, and human resources. To this view, Dougherty (2) adds:

Because they can think, persons can understand their circumstances and the alternatives available to them. Because they can choose, persons can act to affirm or change their circumstances. Because they can think and choose, persons are free to create their own life plans and the values of which they are made.

It follows then, that predominant libertarian values are deeply entrenched in the notion of the self-made person and that social rewards should only accrue if they are deserved and earned. The role of government is, therefore, limited to those functions that absolutely do not abridge the rights of the individual to exert his or her own will for what he or she believes to be best. Moreover, government's role would be limited to those functions and needs for which individuals could not provide (national defense, negotiation of treaties, etc.).

Egalitarian principles focus on the equal moral standing of all individuals regardless of achievement or station in life. This philosophy also centers on the right to equal opportunity and to the extent possible, to be free from need and want. Thus, egalitarianism (2) can be viewed as follows:

Practically, this means an equal right to a reasonable share of those basic goods and services known to be necessary for a decent human life, including a right to a job, minimum income support, or provision in kind of the goods necessary for life, as well as a right to a range of social and health care services designed to prevent and minimize psychological and physical suffering, disabilities, and premature death.

Egalitarian values place specific demands on government and political policy to construct broad services and support systems so that all members of society are provided with equal opportunity designed to prevent and minimize psychological and physical suffering and disabilities, and to achieve one's life's aims. In this fashion, government would act on the entitlements due to all members of society. Such entitlements might be derived from legal or other forms of social consensus.

This range of social values from libertarianism to egalitarianism holds differing beliefs about equality,

justice, opportunity, rights, and the functional responsibilities of government. When this spectrum of social values is held over health, health care, and the administration and financing of health care services, it is not surprising that a vastly different array of designs emerge. Because health and health care are so tightly wound into personal, cultural, and social beliefs, it is not surprising that such a vast array of health care systems and notions about health have emerged across the world.

America's historical foundations have leaned strongly to the libertarian philosophical viewpoint (3). The influence of the "Protestant ethic" from Europe, coupled with the opportunities that a fresh land provided to "become one's own person," are strongly borne out in American society. An unbridled, free-market economy and freedom from governmental intervention in the daily lives of the citizenry are strong values that have been integrated into the American lifestyle and American political economic thought. The notion of "pulling yourself up by your bootstraps" succinctly reflects these dominant social, political, and economic values. Such antecedents are reliable markers for characterizing America's health care system. Consequently, it is a fascinating mosaic of pluralistic approaches. It is a strongly market-driven, industrialized system, which, at the same time, may be described as one of the world's best and one of the world's most troubled systems.

The United States does not have a universal health insurance program characteristic of many developed nations. Nor does it have national health care services like that of the United Kingdom and other nations. Except for those persons in the United States who possess special legal entitlements, the American health care system is largely a private enterprise; in other words, an industrialized system. The providers, payers, and institutions of care represent a rich mixture of private agents, corporations, insurance systems, and governmental agencies. There is not a singular rationalizing source for setting broad-based national policy and direction for the health care system as a whole. Rather, the vast market place of ideas has a variety of options in order to implement any proposal for which someone will pay. Relman has termed this approach "the industrialization of health care" (4).

The role of the national and state governments in the health care system is limited to those entitlement programs that have been legislated into federal or state law or where there is a federal and state partnership. Federal involvement in the provision of health care services began with the U.S. Public Health Service (PHS), an agency of the U.S. government. The PHS was established in 1798 to provide essential health care services to merchant marine

personnel and members of the U.S. armed forces. Subsequent federal involvement in the provision of and the payment for health care has incrementally increased to include care for individuals with special entitlements. The latter include veterans of the armed forces, the elderly, indigent people, Native Americans, persons with HIV/AIDS, certain disabled individuals, and qualifying persons with end-stage renal disease. For example, qualified veterans of the armed forces have access to a federal system of hospitals, clinics, and long-term care facilities under the Department of Veterans Affairs (a cabinet-level agency of the executive branch of the federal government). Since 1965, the federal government sponsors Medicare, a health insurance program for the elderly (65 years of age and over and later the disabled). The federal government also cost-shares with participating state governments to provide the Medicaid program (also enacted in 1965). The latter is an insurance program for health services directed toward qualifying indigent people. In Medicare and Medicaid, institutional and individual providers participate as contractors under a set of specific conditions for participation.

State and local (city and county) governments have limited roles in the provision of health care services. State, county, and city health departments are as differently organized and functioning, as there are states, counties, and cities in the United States. These agencies reflect and represent the special needs of the geographic areas and demographic compositions of their respective domains. Hence, the functioning and expanse of services offered by the New York City Department of Health is vastly different from a similar agency in rural Montana.

This unique approach to the application of a health care system must also be examined in light of the diversity of the demography and geography of the United States. Approximately 273 million people inhabit the United States across a geographic expanse of 3.5 million square miles of land. Ranging from the deserts of Nevada to the Rocky Mountains of Colorado and Wyoming to the tropics of Florida and the oceanic seaboards of the east, west, and southern coasts, American geography and topography is expansive (5). Hence, a substantial challenge to the delivery of health care services exists in this array of geographical areas.

The American population is equally diverse and expansive. There are almost 35 million people who are age 65 or older. African Americans constitute 12.8% of the population, Asian and Pacific Islanders 4%, American Indians 0.9%, and Caucasians make up 82% of the population (5). Because the United States is largely a nation of immigrants, there are literally hundreds of additional ethnic groups that are part of the American

social fabric. As of March 1997, 25.8 million individuals in the United States were foreign-born, which represents a 30% increase from 1990, when there were 19.8 million foreign-born individuals in the United States. Mexico was the place of origin for 7 million or 28% of the total foreign born population in 1997 (5). During 1996 and 1997, 1.3 million people moved to the United States from abroad, and 92% of those individuals moved to metropolitan areas. Additionally, during this time period, 3 million people left the central cities and 2.8 million moved to the suburbs (6). The health care system of the United States should then be viewed in the following context:

- A diverse spectrum of social values, which have historically pointed more toward libertarianism than egalitarianism
- Limited roles of the federal, state, and local governments in the provision of, and payment for, health care services
- A pluralistic, free-market approach to the provision of health care services
- A geographically diverse and substantive land mass
- A culturally diverse and numerically large population whose characteristics are changing toward more elderly and racial and ethnic heterogeneity

It is critical that the reader be sensitive to these contextual variables to understand the American health care system and how health care policy is shaped and implemented in the United States.

THE ORGANIZATION OF U.S. HEALTH CARE SERVICES

Health care services in the United States are provided by a broad array of facilities, which are financed from a variety of payment sources. As of 1998, there were 6021 hospitals (7), 1,012,582 hospital beds, 33,765,940 admissions, and 241,574,380 inpatient days. In 1998, the average length of stay in community hospitals was 6 days, whereas it was 7.7 days in 1975 (7).

It is also notable that the numbers of hospitals in urban and rural settings are shrinking. In 1993, there were 3012 urban hospitals and 2249 rural, whereas in 1998, there were 2816 urban and 2199 rural hospitals (13). The numbers of public acute care hospitals decreased from 1390 in 1993 to 1260 in 1997 (8). Closure of hospitals and simultaneous reductions in hospital beds has occurred in inner city areas where care is provided for large numbers of indigent patients. Such closures are related to the high costs of care, which are not concomitantly reimbursed by state and federal sources

either because the individuals are not eligible or because payment rates do not cover the costs incurred. Small, isolated rural hospitals are facing similar economic and, hence, survival difficulties. The plight of rural hospitals is of special significance because their survival is often linked to the economic and social survival of a rural community.

While the world's population grows at an annual rate of 1.7%, the population over 65 increases by 2.5% per year. There are just fewer than 600 million people over the age of 60 in the world. Approximately 360 million of the world's over 60 population lives in the developing world, in which 7.5% of the population is elderly. In contrast, 18.3% of the population is elderly in the developed world. The most rapid changes are occurring in some developing countries where an increase of 200–400% in the elderly population is predicted over the next 30 years (9). Because of the growth of the elderly population, there has been an increase in the demand for geriatric and long-term care facilities. Over the next several decades, the elderly's health care consumption in the United States will be approximately \$25,000 per person (in 1995 dollars) compared to \$9200 in 1995 (10). In this respect, the United States is following the trends exhibited in most developed industrialized countries.

The increased utilization of health care services by the elderly is expected to put additional strains on an already besieged health care system. Increasing the life span, either through preventive measures or through other acts of distributive justice, solves some problems while creating others. This astounding paradox will assuredly complicate the political and social processes of decision making. Equally likely will be the burdens these phenomena add to an already overburdened national economy.

In the last several years, it is the substitutability that has been emphasized, as more and more procedures are performed in outpatient settings. Many services previously performed in the hospital now take place in physician offices. In 1996, there were 734,493,000 visits to the physician, with an average of 3.4 per person (11), and the most frequent principal reason for a visit was a general medical examination, with a total of 54.7 million in 1996. Also in 1996, there were 67.2 million visits to outpatient departments, and 40.3 million inpatient surgery procedures were performed (11). This analysis points to the increasing importance of the ambulatory care setting as a place for rendering care. The relevance of outpatient care will continue to grow as more medical procedures are performed outside hospitals and greater emphasis is placed on preventive care. Outpatient visits in community hospitals alone have advanced from 263,631,000 in 1986 to 301,329,000 in 1990 to 474,193,000 in 1998 (7).

The National Association of Home Care estimates that more than 20,000 providers deliver home care services to approximately 8 million individuals each year (12). According to the Health Care Financing Administration (HCFA), the average number of home health visits a year per Medicaid beneficiary was 80, compared to 27 visits in 1989. Additionally, the number of home health agencies participating in Medicare has increased from almost 5000 in 1988 to over 10,000 in 1997 (13). Care of patients in home settings is likely to expand as data further suggest reduced cost for such care without compromising quality. Technological and scientific developments related to providing sophisticated treatments in the home will also stimulate growth in this sector of health services.

TRENDS IN HEALTH INSURANCE COVERAGE

According to the President's Advisory Commission on Consumer Protection and Quality in the Health Care Industry, there are five trends that summarize the characteristics of health insurance plans of the late 1990s:

- Increased complexity and concentration of health plans
- Increased diversity of health insurance products
- Increased focus on network-based delivery
- Shifting financial structures and incentives between purchasers, health plans, and providers
- The development of clinical infrastructure for utilization management and quality improvement (14)

In response to rapidly increasing health care costs, private insurance companies and employers (who pay the premiums in whole or in part for their employees) have increased their part in implementing cost-containment strategies. A dramatic effort has been the application of business principles to purchasing and vendor selection and payment for and selection of health care providers and institutions of care.

Private employers, the federal government, and state and local governments invest significant financial resources in health care purchasing expenditures. In 1995, private employers contributed \$183.8 billion to private health insurance premiums, whereas the federal government spent \$11.3 billion on private health insurance premiums, and state and local government spent \$47.1 billion (14). In 1995, more than 83% of the insured population was covered by private insurance, whereas about 31% was enrolled in a public program, such as Medicare or Medicaid.

Probably the most significant change in the American health care system in recent years is the

development of managed care. In managed care settings, the covering company is responsible for providing services, whereas, at the same time, it is exposed to the financial risks of unanticipated services. Health Maintenance Organizations (HMOs) contract with hospitals and certain physician providers for services within a negotiated schedule of fees. HMOs and other such managed care organizations specify where and by whom care is to be given. The latter is a radical departure from the historically preeminent "freedom of choice" that patients and care providers enjoyed under the traditional indemnity and fee-for-service reimbursement programs. The traditional method of paying for medical services is fee-for-service when the provider charges a fee for each service provided, and the insurer pays all or part of that fee.

Managed care is an umbrella term for HMOs and all health plans that provide health care in return for preset monthly payments and coordinate care in a defined network of primary care physicians and hospitals. A network includes physicians, clinics, health centers, medical group practices, hospitals, and other providers that a health plan selects and contracts with to care for its members. An HMO is an organization that provides health care in return for preset monthly payments. Most HMOs provide care through a network of physicians, hospitals, and other medical professionals that their members must use in order to be covered for that care.

There are a number of different types of HMOs. A staff model HMO is an HMO in which the physicians and other medical professionals are salaried employees, and the clinics or health centers in which they practice are owned by the HMO. A group model HMO is made up of one or more physician group practices that are not owned by the HMO but operate as independent partnerships or professional corporations. The HMO pays the groups at a negotiated rate, and each group is responsible for paying its doctors and other staff as well as covering the cost of hospital care or care from outside specialists. An Independent Practice Association (IPA) generally includes large numbers of individual private practice physicians who are paid either a fee or a fixed amount per patient to take care of the IPA's members. A Preferred Provider Organization is a network of doctors and hospitals that provides care at a lower cost than through traditional insurance. PPO members have more health coverage when they use the PPO's network and pay higher out-of-pocket costs when they receive care outside the PPO network (15).

An integrated health system is a network that provides a coordinated continuum of services and is clinically and fiscally accountable for outcomes. There was a significant

growth of integrated health systems during the late 1990s. In 1997, there were 228 integrated systems and, in 1998, there were 266, representing an increase of almost 17% (16). Simultaneously, there has been a disintegration of systems when mergers fail and disassemble. Iglehart comments on how managed care has changed the face of health care:

Before the emergence of managed care, it was largely physicians, acting individually on behalf of their patients, who decided how most health care dollars were spent. They billed for their services, and third-party insurers usually reimbursed them without asking any questions, because the ultimate payers—employers—demanded no greater accounting. Now, many employers have changed from passive payers to aggressive purchasers and are exerting more influence on payment rates, on where patients are cared for, and on the content of care. Through selective contracting with physicians, stringent review of the use of services, practice protocols, and payment on a fixed, per capita basis, managed-care plans have pressured doctors to furnish fewer services and to improve the coordination and management of care, thereby altering the way in which many physicians treat patients. In striving to balance the conflicts that arise in caring for patients within these constraints, physicians have become “double agents.” The ideological tie that long linked many physicians and private executives—a belief in capitalism and free enterprise—has been weakened by the aggressive intervention of business into the practice of medicine through managed care (17).

There has been a recent challenge to the core tenet of managed care that centralized decision making could deliver improved care at a reduced cost. In November 1999, a large health care company decided to allow physicians to choose what care patients need without the insurance company’s intervention or approval. This action opens the door to further discussions about how managed care principles are utilized. Regardless of managed care’s future course, cost containment measures will be necessary to prevent an explosion of health care costs. The demand for cost containment will need to be weighed against the imperative to insure that patients have access to care. Paul Ellwood, often referred to as the “father of the HMO,” believes that there will be a new era in which patients, not employers and government purchasers, will have power (18). Regardless, the weight of political and consumer pressures, along with experience and economic efficiency, will determine the future of managed care.

HEALTH CARE FINANCING

The expenditures for health care in the United States have grown from \$51 billion in 1967 (6.3% of GNP) to over \$1 trillion in 1997 (14% of GDP).^a In 1997, on a per capita basis, \$4090 was spent on health care (19) and 0.64 per day/capita was spent on prescription drugs (20). This is substantially higher than that of other industrialized nations. When comparing health expenditures in the major industrialized countries comprising the Organization for Economic Cooperation and Development (OECD), for example, dramatic differences in per capita expenditures are noted (21). Such differences also exist in the percentage share of GDP spent on health care (21), and relative growth in health care expenditures over time varies greatly among these countries (21, 22).

The Health Care Finance Administration asserts that national health expenditures are projected to total \$2.2 trillion and reach 16.2% of the GDP by 2008. The growth in health spending is projected to average 1.8 percentage points above the growth rate of the GDP for 1998–2008. This differential is higher than recent experience but remains below the historical average for 1960–1997, where growth in health spending exceeded growth in GDP by close to three percentage points. There are a number of factors that contribute to the projected acceleration, including:

- An increase in private health insurance underwriting cycle
- A slower growth in managed care enrollment
- A movement towards less restrictive forms of managed care
- A continued trend toward increased state and federal regulation of health plans

The growth of health care expenditures without a concomitant gain in health status of the population is receiving more and more attention on the governmental and corporate agenda. On the governmental level, an increasing proportion of federal and state budgets is being allocated to health care. In the private sector, corporations and individuals are bearing larger proportions of health care costs. Although no particular percentage of GDP has been determined to be an acceptable or unacceptable expenditure for health care services, the fact is that costs are increasing and the health care sector is gaining an increasing share of the economy. This follows several other interesting trends. During the period of 1961 to 1997,

^aThe GNP is the total annual flow of goods and services in a nation’s economy. Most industrial countries now use GDP, which measures the value of all goods and services produced within a nation, regardless of the nationality of the procedure.

national health expenditures as a percentage of GNP rose from 5.4% to over 14%. In the same period, dramatic differences occurred in the source of revenues for health care expenditures. The pattern of spending these resources also changed significantly (13).

In 1960, 49% of health care revenues came from out-of-pocket payments from individuals. Out-of-pocket spending is defined as expenditures for coinsurance and deductibles required by insurers, as well as direct payments for services, which are covered by a third party. In 1990, individual consumers spent \$144.4 billion directly for out-of-pocket payments for personal health services (23). This accounted for 38% of all personal health spending. In 1998, consumers spent \$183.7 billion in out-of-pocket payments, which accounts for 33% of the \$558.7 billion in personal health spending (23).

Consumers have spent and continue to spend less of their own personal money for health care services. This decrease in personal spending has been shifted largely to third parties, such as private health insurance, government programs, philanthropic organizations, and other sources. It is evident that the shift away from personal, out-of-pocket health spending has resulted in greater consumption of health care services. This transition reflects the general maxim in health care economics that the consumption of health care services is probably insatiable (24). Moreover, unlike other sectors of the economy and the laws of economics they obey, prices for health care services do not fall with increased consumption or purchasing.

According to Iglehart, the decline in personal spending is "attributed in large part to the growth in health maintenance organizations (HMOs), which traditionally offer broad benefits with only modest out-of-pocket payments. In the past few years, however, most HMO enrollees have had increased cost-sharing requirements, as employers and health plan managers have sought to constrain spending even further. Out-of-pocket payments are still considerably less in an HMO than with indemnity insurance (17)." However, "The overall declines in per capita out-of-pocket spending mask the financial difficulties of many poor people and families. A recent study estimated that Medicare beneficiaries over 65 years of age with incomes below the federal poverty level (in 1997 the level was \$7755 for individuals and \$9780 for couples) who were also eligible for Medicaid assistance still spent 35% of their incomes on out-of-pocket health care costs. Medicare beneficiaries with incomes below the federal poverty level who did not receive Medicaid assistance spent, on average, half their incomes on out-of-pocket health care costs (17)."

Historically, a lack of public insurance programs created obstacles to health care services. For those who could not

afford to pay for private insurance, the costs associated with health care were larger than most could afford. After lengthy debate, the U.S. Congress passed legislation in 1965 that established Medicare and Medicaid. Medicare covers over 95% of the elderly in the United States as well as many individuals who are disabled. Coverage for the disabled began in 1973 and is divided in two parts: 1) hospital insurance and 2) supplementary medical insurance. The total disbursement for Medicare in 1997 was \$213.575 billion, and there were 36,460,143 enrollees, of which 32,164,416 were elderly.

The total expenditure for the Medicaid program was \$160 billion in 1996. Of the total amount spent in 1996, Medicaid payments for nursing facilities and home health care totaled \$40.5 billion for more than 3.6 million recipients. The average cost per recipient in 1996 was \$12,300, and almost 45% of the total cost of care for individuals using nursing homes and Medicaid was paid for home health care (13).

Since the enactment of Medicare and Medicaid, there have been various legislative and administrative changes. The Balanced Budget Act of 1997 enacted the most significant changes to Medicare and Medicaid since its inception, including a capped allocation of monetary resources to states and the addition of the Children's Health Insurance Program. The Children's Health Insurance Program set aside \$24 billion over 5 years for states to provide health care to over 10 million children who are not eligible for Medicaid.

In 1960, public programs paid for one quarter (24.5%) of all health care spending; by 1988, this share had increased to 42.1%. Together Medicare and Medicaid financed \$351 billion in health care services in 1996, which is more than one-third of the nation's total health care bill. Additionally, it represents three-quarters of all public spending on health care. There has been a significant increase in Medicare managed care enrollment—from 3.1 million at the end of 1995 to 6.3 million in 1999, leaving approximately 33 million beneficiaries in a traditional fee-for-service Medicare program.

An area of controversy is the limitation on coverage for prescription drugs. Spending on prescription drugs is the fastest-growing piece of personal health expenditures, amounting to \$78.9 billion in 1997. Additionally, spending for prescription drugs has increased at double-digit rates: 10.6% in 1995, 13.2% in 1996, and 14.1% in 1997 (17). The reason for this rapid growth, according to Iglehart, includes: "Broader insurance coverage of prescription drugs, growth in the number of drugs dispensed, more approvals of expensive new drugs by the Food and Drug Administration, and direct advertising of pharmaceutical products to consumers. The use of some new drugs reduces

hospital costs, but not enough to offset the increase in expenditures for drugs (17).” In the year 2000, 86% of health care plans will have an annual limit on brand and generic drugs, and there will be increased use of copayments for prescription drugs (25).

The budget cuts imposed by Congress in 1997 to help balance the budget have restricted the fees that caregivers receive for the elderly and disabled. When federal health programs cut funding significantly, as occurred in the Balanced Budget Act of 1997, the resulting cutbacks at the institutional and health-system level trickled down to providers’ abilities to provide an acceptable level of service designed to protect patient safety and foster appropriate medication use. Partial restoration of the Balanced Budget Act in 1999 addressed the transition to an outpatient prospective payment system for hospitals, payments to skilled nursing facilities and home health agencies, payments for indirect medical education, and a number of rural health care provisions.

The dramatic shift of third parties (government, private health insurance) toward paying for a greater and greater proportion of personal health care services has led to a paradigm shift in attitudes and actions toward health care financing and cost control. Several approaches have been adopted in the governmental sector to slow the increases in costs and expenditures. The most dramatic of these has been the introduction in 1983 of the prospective payment system (PPS) to curb the growth in hospital costs and expenditures. By imposing prospective limits on Medicare payments to hospitals through a system of reimbursing average costs of specific diagnoses, hospital utilization has decreased dramatically. The average length of stay and admission rates in community hospitals of elderly patients (those covered by Medicare) dropped sharply after the introduction of PPS (13).

Because of cost-containment strategies of both the private and governmental sectors, hospital utilization has declined. This has resulted in a decline in the number of patient beds, the average length of stay, and patient bed census (7). The present predominant view is that hospitalization of any patient, regardless of revenue source, is to be avoided wherever possible. Only those patients for whom hospitalization can be fully justified are admitted.

As much as the financing of America’s health care system is a major issue on the policy agenda of the nation, so too is the continuous question about the relationship between the costs and the outcomes of care. As costs increase, the numbers of policy analysts, organizations, and governmental agencies calling for a better definition of the cost-outcome relationship has sharply risen.

Cost-effectiveness and cost-benefit analyses are frequently mentioned in academic and policy-analysis

circles. These notions center on careful examination of the costs and their corresponding outputs. Eisenberg (26) defines cost-effectiveness analysis as the measure of the net cost of providing service (expenditures minus savings) as well as the results obtained (e.g., clinical results measured singly or a series of results measured on some scale). Cost–benefit analysis determines whether the cost is worth the benefits by measuring both in the same units (26). Such analyses will be critical, as future policy decisions are made with regard to the collection, allocation, and utilization of finite resources in the health care system for the enhancement of health status of the American people.

Private-sector strategies and governmental plans to curb health care costs have not escaped criticism. Ginsberg, for example, argues that the notion of “for profit” hospital chains has severe limitations with respect to garnering large proportions of market share and, consequently, greater profits (27). He bases this view on the limited amount of private funding available for hospital care. On the other hand, he sees this sector as being able to grow in the area of nursing homes and other businesses related to the care of the elderly.

ACCESS TO HEALTH CARE SERVICES IN THE UNITED STATES

There are three classes of individuals who have open access to and can derive some form of services from America’s health care system:

- Those who receive support from governmental sources because of specific entitlements (indigents, elderly, and veterans)
- Those who are provided with basic health insurance coverage from their employers
- Those who choose to cover their expenses from out-of-pocket payments

There are, however, those who have no specific financial support or capacity to pay for health care services and who are not eligible for any type of entitlements. These individuals must rely on some form of charity care or services. In addition, there are those who, for reasons of geographic remoteness or total inability to gain access, have no access to health care services. This group represents a complex, resource-based demand model, which also has an equally complex pattern of health care system and services-utilization requirements.

With increasing health care costs and consequent increases in insurance premium costs, gaining access to

health care services without incurring personal costs has become more difficult. Not all services are covered for individuals in the federal Medicare and Medicaid programs. Moreover, there are strict limitations on the extent of services offered in these programs. A similar set of restrictions may be found in private-sector health care coverage strategies. Because few insurance programs and none of the federal programs provide coverage for unlimited long-term care, all but the very rich are at risk of financial ruin.

The health care lexicon includes two new terms to reflect these problems: underinsured and uninsured. The underinsured may include the “working poor,” those individuals who have jobs and may be covered by a very limited, if any, health insurance program by their employers. They are likely low wage earners and those receiving incomes at, or slightly above, the poverty level. Typically, they do not qualify for Medicaid entitlements, do not have employer-paid health insurance benefits, and cannot afford (or choose not to purchase) third-party coverage for payment of health care services.

There are no specific policy plans available to finance uninsured and underinsured care. Whether planned as charity care or unplanned as financial loss, the “price tag” for uncompensated care in the United States was \$18.5 billion in 1997, which is 6% of the total of hospital expenses (28). This percentage has remained constant since 1984, when the percentage of total expenses for uncompensated care was also 6% (8).

Reduced payments and high levels of uncompensated care have led to the closing of hospital facilities in both urban and rural blighted areas, making access to care even more difficult for some. Whiteis and Salmon (29) refer to this phenomenon as “disinvestment in the public goods.” Because privately owned and not-for-profit hospitals and private clinics, pharmacies, and physician’s offices must rely on their own financial soundness, any threat to that foundation may lead to closure.

The amount of uncompensated care is magnified in areas where serious social problems exist because health status is directly related to social status. Health status should be examined in broad terms by reviewing morbidity and mortality data available for the whole population. The life expectancy of people who live in the United States has grown by almost 10 years, from 68.5 years in 1936 to 76.1 years in 1996. Women were expected to live to 79.1 years in 1996, whereas the average for men was 73.1 years (11). The leading causes of death in 1996 among people living in the United States were (11):

1. Heart disease (733,361 deaths)
2. Cancer (539,533 deaths)

3. Stroke (169,942 deaths)
4. Pulmonary diseases (108,027 deaths)
5. Accidents (94,948 deaths)
6. Pneumonia and flu (63,727 deaths)
7. Diabetes (61,787 deaths)
8. AIDS (31,130 deaths)
9. Suicide (30,903 deaths)
10. Liver disease (25,047 deaths)

Infant mortality, another measure of the health status of a nation, stated as the number of deaths per live births, was 7.2 per 1000 live births in 1997 compared to 9.9 per 1000 live births for 1988. Overall, these figures are comparable to those of the major, industrialized nations of the world.

Major morbidity in the United States is currently centered on diseases of life style. These morbidities contrast sharply with disease patterns prevalent during the early part of the 20th century. Outside of AIDS and other sexually transmitted diseases, infectious diseases represent a small proportion of prevalent morbidity. Rather, life-style diseases, associated with smoking, poor nutrition, a sedentary life style, alcohol and other chemical consumption, homicides, suicides, and accidents, represent the majority of morbidity in the United States. Significant preventive strategies can markedly reduce the incidence, prevalence, and mortality associated with these health care problems.

Not surprising, in areas with high concentrations of indigent people, there are similarly high concentrations of uninsured individuals requiring intense health care services. These areas exist in both rural and urban settings. Emergency rooms have become a major resource for primary health care services in areas where physician office services or other service providers (clinics) are not available because of location, cost, or quality. Emergency rooms have also become providers of high-intensity care for victims of gun shot wounds, drug overdoses, communicable diseases, and other trauma associated with poor social conditions. Much of the care in emergency rooms is uncompensated because the quality and amount exceed the allowable reimbursement. Some trauma centers in economically blighted areas have been closed (30).

Hospitals in inner cities and blighted rural areas also care for a higher proportion of “at-risk” patients than hospitals in the for-profit sector generally located in more affluent areas (29). In fact, affluent hospitals sometimes “dump” their uncovered patients on charity care and other public hospitals in order to reduce their financial risks. This, however, increases the financial risks of public or charity hospitals. Again, the reimbursement levels under present schemes for large numbers of “at-risk” patients simply do not cover costs; thus, the United States has

witnessed hospital closings, particularly in those areas where such loss is most noticeable (30).

American health policy continues to grapple with these issues related to the underinsured and the uninsured (31). A multiple-tiered health care system based on social class and ability to pay is unacceptable in a nation that boasts incomparable riches and political agendas of democracy and rights. Ginsberg (27) notes:

Despite all our efforts of recent years, then, health care costs continue to increase.... There is undoubtedly waste in the health care system, but no solid proposals have been advanced to recapture the \$100 billion, plus or minus, that some believe can be saved. I believe that we will not reshape our national health policy agenda unless and until we achieve a broad consensus on the key issues. Do the American people, for example, desire to ensure access to health care for the entire population? In that case they must agree to pick up a sizable additional tab, which they have thus far avoided.

The issue of quality health care has become an increasing issue of concern in the face of cost constraints and limited access to health care. The *President's Advisory Commission on Consumer Protection and Quality in the Health Care Industry* (32) states that "the purpose of the health care system must be to continuously reduce the impact and burden of illness, injury and disability and to improve the health and functioning of the people of the U.S." According to the Commission, there are basic characteristics of health care that, as a nation, we should strive to achieve. The Commission has created "Guiding Principles for the Consumer Bill of Rights and Responsibilities" for the health care of people in the United States. These include the following:

- All consumers are created equal.
- Quality comes first.
- Preserve what works.
- Costs matter.

THE FUTURE OF HEALTH CARE

Suggestions for broad reform, which address the financial, access, and quality of care issues for America's health care system, have emerged during the past decade. Iglehart emphasizes the irony of the American health care system. He writes (17):

By many technical standards, U.S. medical care is the best in the world, but leaders in the field declared

recently at a national round table that there is an "urgent need to improve health care quality." The stringency of managed care and a low inflation rate have slowed the growth of medical spending appreciably, but a new government study projects that health care expenditures will soon begin escalating again and will double over the next decade. In short, the American system is a work in progress, driven by a disparate array of interests with two goals that are often in conflict: providing health care to the sick, and generating income for the persons and organizations that assume the financial risk.

The President's Commission (32) outlines areas in which the American health care system could be improved in light of the reality that many individuals receive substandard care and 44.3 million individuals are without health insurance coverage. This commission outlines several types of quality problems including avoidable errors, underutilization of services, overuse of services, and variation in services. Based on the reality of these quality problems, the Commission recommended that the initial set of national aims should include (32):

- Reducing the underlying causes of illness, injury and disability
- Expanding research on new treatments and evidence on effectiveness
- Ensuring the appropriate use of health care services
- Reducing health care errors
- Addressing oversupply and undersupply of health care resources
- Increasing a patient's participation in his or her care

The President's Commission engages a broad consumer advocacy movement in public and private sectors calling for a major reform of the U.S. health care system to improve access to care for more individuals living in America. Consistent with previous patterns, however, these calls have only led to incremental adjustments in policy and slight quality changes in direction. The major problems, for the most part, remain unaffected. Although broad based health care reform efforts have been unsuccessful, market forces and more targeted legislation and regulatory efforts have changed the face of health in the 1990s.

The 1993-94 Clinton health care reform plan, in its ideology, provided an ambitious plan to eliminate the enormous problem of lack of access to health care. It proposed to guarantee comprehensive health benefits for all American citizens and legal residents, regardless of health or employment status. The proposal was unsuccessful due to a number of factors, including its vast scope, the complicated nature of the plan, and an underestimation of

the politics involved with radically reforming health care. The failure of the Clinton administration health care reform agenda and the subsequent events to revise the American health care system are important lessons of health-care-system related politics.

Unfortunately, since the failure of the Clinton Administration plan in 1994, the number of uninsured individuals in America has grown. According to the Census Bureau, 44.3 million people are uninsured, comprising about 16.3% of the population. Of those uninsured, 15.4% are under 18 years of age, and the largest percentage is among individuals between 18 and 24 years of age. People of Hispanic origin make up 35.3% of those uninsured and 43% of the total uninsured population are not citizens of the United States (6).

The number of uninsured persons is expected to continue to grow. Proposals for health care reform to combat this problem include President Clinton's proposal for Medicare buy-in proposals for "middle aged" adults and House Majority Leader Dick Armey's (R-TX) proposal for a refundable tax credit to pay for insurance for the uninsured. The 2000 presidential campaign opened the debate for legislation that will improve health care coverage for the uninsured. This public debate on how to enhance access to care will stimulate creative ways to improve the U.S. health care system. However, rhetoric is not enough; it needs to be translated into programs that attack the problem.

The essence of the health care financing dilemma is related to how much a nation wishes to spend, on whom these funds are to be expended, and by what methods a relationship among cost, quality, and outcomes might be determined. In a time when advancing science and technology is flourishing in the health care field, "high tech" medicine will continue to evolve with an ever-increasing price tag. Furthermore, the costs of unanticipated and complex disease problems (e.g., HIV/AIDS) add to the unpredictability of health care system costs. This is all to say that most policy makers understand what needs to be done. They are in a quandary, however, in finding the appropriate and acceptable solution. Hence, it is likely that costs and expenditures will continue to rise (and, thereby, increase the percentage of GNP that will be spent for health care) and that solutions may become even more elusive.

Although some might argue that the available resources for expenditures on health care are ultimately limited, few are able to say exactly where that limit is or should be. In the United States, there has been an expansion of technologies and procedures based on scientific advancements without a concomitant development of a moral and ethical policy for determining who might be best served by such advancements. Rationing of health care services or

otherwise limiting access to high cost services, for example, has resulted from political policy rather than from deliberated public policy and rational decision making. This is most notably evidenced in the Medicaid component of the U.S. health care system.

As cost pressures continue to mount, there will likely be a return to having patients pay more of the health care expenditure dollar from their own resources. This will take the form of higher deductibles and co-insurance payments. Perhaps returning the burden of health care financing to the individual will raise the collective consciousness of American society that "there is no such thing as a free lunch" insofar as using and paying for health care services is concerned. Certainly, this phenomenon has occurred in social welfare "reform" in which the programs that have had mixed success have been restructured to "roll" participants off of welfare to work.

On the other hand, there are perhaps no solutions forthcoming on some of the problems represented in the arena of health care financing. As Hardin suggests, there is indeed a class of human problems that have no technical solution (33). In using Hardin's analogies, Hiatt (34) suggests that "nobody would quarrel with the proposition that there is a limit to the resources any society can devote to medical care, and few would question the suggestion that we are approaching such a limit. The dilemma confronting us is how we can place additional stress on the medical commons without bringing ourselves closer to ruin."

CONCLUSION

These are the principal contemporary features of the U.S. health care system. A massive societal structure is at once saviour, behemoth, juggernaut, and question mark. It certainly will be in a constant state of flux and gradual change. It therefore bears constant vigilance and careful guidance by those who derive their livelihoods from it and those who are the beneficiaries of its caring. Most importantly, it will require significant pressure from those who are disenfranchised from it.

HEALTH CARE SYSTEMS: OUTSIDE THE UNITED STATES

Albert I. Wertheimer

Temple University, Philadelphia, Pennsylvania, U.S.A.

Sheldon X. Kong

Merck & Co. Inc., Whitehouse Station, New Jersey, U.S.A.

INTRODUCTION

It is quite fascinating how the organization, structure, and financing of health care services can be so very diverse in different countries around the world. One might think that leaders and policymakers would be aware of each other's national health systems and, by emulating the best features, that they would tend to move toward harmonization and greater similarity.

Actually, this assumption is false. National health care systems vary widely and are more related to variables in each country (1). In fact, the health system in a given country is a mirror of how that society functions at large. Health care delivery systems must be compatible with the: 1) *economic system*: socialist, capitalist, or mixed; 2) *political system*: major or minor role of degree of government centralization; 3) *wealth of the country*: use of primary care facilities, access to specialists and tertiary care facilities; 4) *traditions and conventions as seen in their history*—fundamental, visible things are difficult to change; 5) *geography*: whether the majority of the population is located in a few metropolitan areas, with the remainder scattered in rural areas, or whether the population is spread over hundreds of islands; 6) *infrastructure*: roads, communication systems, and air service; and 7) *extent of and belief in high technology* (2).

There are other factors as well: the system from a previous colonial power, extent of literacy and education, and relationships with outside countries, to name a few.

BACKGROUND

The remainder of this article examines the health care delivery systems in six very different countries. Even though Canada and the United States are similar countries with a shared border and language and with open

communication, their health care delivery systems could not be any more different. Each side of the border is aware of what happens on the other side, however, a series of complex and powerful forces keep them moving in their own directions.

We look at six countries very briefly in this article to highlight the incredibly diverse approaches to health service organization and financing. In essence, most health systems fit into one of the following models:

1. State ownership and control—The best examples are the British National Health Service and the Swedish system in which clinics, hospitals, and most service providers are owned and operated by the government (3).
2. State health insurance program—Here, the government is the sole or major payer. However, some of the facilities and resources are in nongovernment hands. This is the case in much of Europe (4).
3. Mixed systems—This is seen in much of Asia and Central America and usually where there is a small wealthy class and a massive lower class. The lower class receives care from public facilities, and the small upper class uses private-sector, fee-for-service, and self-paid care.

Other scenarios fit into this category as well. The United States has several independent health care systems including the military, veterans, Medicaid (a federal program for the medically indigent), Medicare (a federal insurance program for those 65 years of age and older), private-sector for-profit, and not-for-profit clinics, hospital chains, managed-care organizations, religious, prison health, and university teaching facilities (5).

4. Exclusively private sector—This category is shrinking as nations realize that health maintenance and disease prevention/wellness are important to their national goals of strength and productivity. Switzerland would still fit into this category, where most health care resources are in private hands (6).

SPECIMEN NATIONAL SYSTEMS

Canada

Organization

Canada uses a national health service, which provides medical services and hospital care to its entire population. The individual provincial governments operate health plans that conform to national legislation but can differ in various aspects. This “Medicare” program guarantees comprehensiveness, universal access, portability, and public administration (7).

Health Canada is the national, federal health agency; however, the operation of health service provision is delegated to the provincial governments, which control virtually 100% of Canada’s hospitals. There is a gatekeeper primary health care system, with GPs (general practitioners) or primary care family doctors serving as the entry point. Access to specialists, diagnostic testing, hospitals, and others is through the GP. Individual citizens have the freedom to choose their own doctors, 95% of whom are self-employed in private practice. The provincial government pays these doctors on a fee-for-service basis.

The individual provincial governments offer different supplemental benefits not covered by the national Medicare program, such as drugs, dental care, and vision care to the poor, elderly, and other specific groups. Supplemental benefits for the typical, employed, and nonelderly person come from the purchase of supplemental health insurance from private sources (8).

Pharmaceuticals

Canada created the Patented Medicine Prices Review Board (PMPRB) in 1987 to guarantee that pharmaceutical products would not have excessive prices in Canada. The board reviews prescribed and over-the-counter (OTC) prices and publishes annual guidelines for manufacturers. Compliance with PMPRB guidelines is voluntary; however, since 1993, the board has the authority to reduce excessive prices and return the excess amount to the government, and to punish the manufacturer.

The PMPRB compares prices in Canada with those in seven industrialized nations (France, Germany, Italy, Sweden, Switzerland, the United Kingdom, and the United States) to ensure that Canadian prices are in line with those of comparable countries. There is some controversy that existing drug products are well-controlled regarding prices, but that such is not the case with newly introduced pharmaceuticals.

Further controls exist at the provincial level at which each province maintains a published formulary of drugs that are reimbursable along with the reimbursement level. Quebec, observers perceive, lists nearly all new drug products, whereas Ontario appears to be slow to list newly approved products. Each province has additional control mechanisms. Ontario requires the first generic drug to be at least 40% less costly than the branded originator product. Some components of the reference price system are seen in British Columbia and Newfoundland.

There is growing harmonization among the provinces; however, there is still no national, standardized, and interchangeable list of drugs for ambulatory care use. In hospitals, drugs that are administered are paid for by Medicare. Each province has interesting and different features in its drug benefit plan.

The Prince Edward Island plan pays for seniors; welfare recipients; nursing home patients; and those with rheumatic fever, diabetes, tuberculosis, multiple sclerosis, AIDS, and several other conditions. New Brunswick has an annual copayment cap for seniors and for organ transplant recipients and for selected other patient categories. A copayment is set at approximately \$9 (Canadian) but is waived for some groups in Quebec, along with an annual copay ceiling of \$750.

Other interesting features of the Canadian system include its 1998 mutual recognition agreement with the EU, prohibition of prescription drug advertising to consumers, a 20-year patent exclusivity period, and the establishment of the PMPRB to ensure fair pricing of medications (9, 10).

Republic of South Africa

Organization

The Republic of South Africa (RSA) has a most diverse health care environment, with world-class practice and facilities in wealthy urban areas and some of the most primitive care in poor remote villages, with a vast array between these extremes. Primary care is now the focus of the ANC government in an effort to correct years of neglect and undemocratic practices under the earlier apartheid-oriented regimes. Public health services are being brought to the Black townships as rapidly as resources permit (11).

However, there are virtually no funds for new drugs against HIV infection in patients, a problem most prevalent in the RSA. To maximize the value of its drugs budget, the RSA has enacted legislation to create an Essential Drugs List for the public sector, along with generic substitution authority, the removal of some pharmacists’ unique

professional privileges, and legislation permitting the parallel importation of pharmaceutical products already registered in the RSA. Obviously, this conserves resources, stretching them for more patients, but this angers the RSA and multinational pharma firms.

South Africa is still the wealthiest country in Africa, with a (1997) GDP at approximately \$130 billion. It must be noted, though, that aggregate numbers hide massive racial differences. It is improving, but the standard of living for Blacks is yet only slightly better than it is in neighboring countries, whereas whites enjoy a standard of living similar to that found in North America or Western Europe. An unemployment rate of over 30% (mostly among Blacks) exacerbates the fiscal situation (12).

Routine immunizations for children, conforming to the World Health Organization (WHO) recommended schedule is the governmental policy, but it is not yet accomplished in all regions. Infectious diseases including HIV remain a serious challenge. Planning and budgeting for resource allocation are difficult because accurate census figures do not exist. Total health expenditures appear to be in the area of \$300 per person per year, and it is estimated that the private sector accounts for greater than 50% of total expenditures.

Public-sector expenditures emphasize primary care, lately, at the expense of tertiary care facilities. Private-sector spending is primarily through private "medical schemes." These are nonprofit organizations supported by employer associations and employees. There are slightly fewer than 200 of these schemes, providing insurance and care payment for nearly 3 million workers and their 5 million dependents (of a total estimated RSA population of 40 million). The largest area of medical scheme expenditure is for medicines, which causes the pressures on pharmaceutical pricing addressed below. After drugs, the next largest expenditures are for private hospitals, medical specialists, general practitioners, and dentists (13).

The RSA Department of Health (DOH) has totally restructured the previous apartheid system of racial and provincial health systems into a coordinated national health program operated through health regions and local health districts. Still, there are major differences in knowledge, education, expectations, and wealth within different subpopulations (14, 15).

Pharmaceuticals

Until recently, manufacturers were free to establish their desired price for a drug. Wholesalers and retailers added what they chose to reach the retail selling price for medications. In 1997, a proposed scheme of prices extending to the retailer was agreed on, but resistance was met from the Pharmaceutical Manufacturers Association(PMA). In the

legislation, a pricing board composed of members selected by the Minister of Health would establish prices for each product and a maximum selling price. Public-sector primary care drugs are reimbursed 100% by the government. Hospital care outpatient drugs can have copayments. The Essential Drugs List would be the core of what is to be available at public facilities, but there appears to be a long way to go before most of these agents will be regularly available on a consistent basis at primary care centers or at public hospitals (13).

The parallel importation of RSA-registered drugs available at lower prices abroad is the basis for PMA litigation against the Drug Legislation of 1997. In addition to the price-setting committee, DOH efforts to encourage the use of generic drugs has proven to be a source of conflict. Other features of the new legislation bar dispensing samples or making bonus payments to dispensers of medicines; the creation of a Code of Ethics for pharmaceutical marketing; and a series of safety regulations, dealing primarily with limiting practice to fully qualified and licensed professionals.

There is a fast lane for new drug approvals if the product is already in at least one of the following jurisdictions: the United Kingdom, Canada, United States, Sweden, or Australia. Approximately 85% (by value) of pharmaceuticals go through the nearly 3,000 community pharmacies. Yet, approximately 80% of the population rely on the public sector for drugs, received through clinics, hospitals, primary care posts, or military facilities. Although there is a 20-year patent period of exclusivity/protection, the parallel imports option effectively defeats this protection.

It will be interesting to see how the access to drugs, price controls, and quality improvement forces will interact and what the actual situation will be in South Africa in the coming years, especially as the country complies with intellectual property and World Trade Organization policies and rules (16).

Japan

Organization

After North America and before Western Europe, Japan is the second largest pharmaceutical market in the world. Its population of 126 million spends \$70 billion on pharmaceuticals each year. On average, each Japanese resident spends \$2000 each year on health care with \$550 of that on pharmaceuticals. Perhaps the primary single features of the Japanese market are the above-average proportion of elderly in the population and the higher than usual consumption of drugs. It has been estimated that by the year 2050, nearly 30% of the population will be older

than 65 years of age. The high consumption rate is attributed to drugs being injected and/or sold by the physician, a practice used, in part, to increase the total price of an office visit (17).

The primary funding source for health services in Japan is the Social Insurance System (SIS), made up of employee programs that pay for nearly 55% of care. The Medical Service for the Aged program covers another 35% of care. Private expenditures and a very small portion for public health promotion and disease prevention make up the difference. The Ministry of Health and Welfare (MHW) maintains overall responsibility for health care services and functions via a number of bureaus. Numerous sources comment that regulations are difficult to understand and interpret, often overlapping, and that this serves as a barrier to foreign firms desiring to enter a market. Physicians, for example, are authorized to own and operate hospitals, effectively excluding corporate owners or physicians not licensed in Japan (18).

Universal health insurance was established in 1961. Nearly the entire population is covered through the employer plans or through programs for the unemployed, retired, or self-employed. Employees pay 10% of the cost of treatments, up to an annual ceiling, and also pay a portion of their premiums, with their employers.

Pharmaceuticals

The MHW sets prices for reimbursable drugs (those approved for the Social Insurance System). Physicians, clinics, and private hospitals are reimbursed at a price slightly higher than their actual acquisition cost. The government has scheduled annual reductions in the reimbursement prices to reduce this source of additional income to physicians. Patients make copayments of 20%, although for children and low-income elderly the copayment is waived, and recently a plan to eliminate copayments for persons 70 years of age and older was introduced.

The MHW reductions of 5–10% of the prices of existing drug products appear to have had the opposite of the intended impact. Doctors are prescribing more of the newest, high-priced pharmaceuticals that have not had their margins reduced yet, thereby earning a bigger amount from the wider difference between their actual cost and the listed reimbursement amount.

With regard to generic drugs, astute observers believe that the Japanese government wants its R&D-intensive firms to be successful. A regulation requires generics to be priced at not less than 40% of the innovator brand price. It is reasonable to assume that the margins (Yakkasa) for physicians are lower with generic drugs, and that these margins will continue into the future, as will the reference price scheme (19).

There is a Japanese pharmacopeia that sets official standards and diverse government agencies that perform tasks undertaken by an FDA. It is rumored that the Japanese will establish a Western-style FDA in the near future.

One of the most disliked regulations in the view of foreign and multinational pharmaceutical companies is the requirement for duplicative clinical trials with humans in Japan, because those carried out elsewhere are not recognized. Also of interest is the fact that Japan, like Korea and Taiwan, has no separation between prescriber and dispenser of drugs. Called “Bungyo,” it is a major source of revenue for doctors and clinics. Fewer than 20% of prescriptions ever reach a pharmacy for dispensing (19).

Good post-marketing surveillance practices (GPMSP) rules have been in place since 1993. Postmarketing experience reports are to be sent to a government agency. Both GPMSP and periodic safety reporting requirements are in place that require a review of the product each year while it is in its re-examination period, immediately after marketing approval. Unlike in the United States, where a new drug application is approved for an indefinite period, in Japan, there is a periodic full reassessment. Such re-evaluations are conducted every 5 years once the initial re-examination period for a drug product has ended.

Drug products are distributed primarily via the 2000 wholesalers, and in addition, there exists a small second channel with drugs going directly to hospitals, GPs, and pharmacies. There are approximately 66,000 pharmacies, most of which are family-owned independents. There are chains as well. However, a growing market for OTCs is found in convenience stores.

Physicians administer and sell drugs to patients as a highly profitable sideline. The incentive is for the physician to use as much of the most costly drug products as possible. There is only a small OTC market, because physicians try to prescribe and dispense as much as is possible. Other than some concern about a drug lag, the pharmaceutical environment in Japan is robust. Periodically, there are calls to separate prescribing and dispensing; however, this is not likely in the near future given the powerful forces backing the status quo (20).

United Kingdom

Organization

With a population of more than 60 million and GDP per capita of more than US \$22,000, the United Kingdom is one of the richest nations in the world. It is one of the G7 countries, a member of the European Union, and a member of the Organization for Economic Co-operation and Development (OECD).

In 1996, total health care expenditure in the United Kingdom was approximately 7.0% of the GDP. Public expenditure by the National Health Service (NHS) accounts for most of the health care costs. The NHS was set up after World War II, with the aim of unifying health care services by voluntary and local hospitals. The NHS offers free health services to all U.K. residents, funded through general taxation.

Two of the major characteristics of the U.K. health care system include health authorities responsible for hospital services and GP fundholders responsible for primary care. In 1996, 100 health authorities became operational in England, responsible for the provision of NHS hospital and community health services covering geographic boundaries with populations ranging from 125 thousand to over 1 million. There are four levels of hospital services. At the community level, community hospitals offer basic medical care for the treatment of acute cases and patients requiring convalescent and long-term/terminal care. General practitioners are the key staff here. At the district level, district general hospitals operate the key acute units, serving an average population of a quarter-million. At the regional level, major specialty services such as neurosurgery, open-heart surgery, and radiotherapy are provided. At the national level, highly specialized hospitals provide complex services for parts or for the entire country (21).

GPs are the gatekeepers and fundholders of the health care system. The principle of fundholding is that GPs manage their own budgets. They can obtain a defined range of services from hospitals and manage patients at the GP level whenever possible to reduce costs. In the late 1990s, GPs fundholders were organized into Primary Care Groups (PCGs). These networks of GPs cover wide geographic areas with an average population of 100,000. In 1999, there were 481 PCGs in England and Wales, and all have unified budgets (e.g., drugs, hospital care services). With a population of a small to medium-sized HMO in the United States, these PCGs have a very broad influence on patient health care and the selection of drugs through formularies.

Pharmaceuticals

The regulatory authority in the United Kingdom is the Medicines Control Agency (MCA) under the Department of Health. The agency's responsibilities include drug licensing, clinical trials licensing, pharmacovigilance and drug safety, communication and provision of information on medicines, inspection of facilities and enforcement of regulations, and the *British Pharmacopoeia*. The United Kingdom is a reference member state for the European Union mutual recognition procedure. The European Union's pharmaceutical registration system came into

effect for all member countries in 1995. The aim of the EU system is to harmonize pharmaceutical regulations throughout the EU. The centralized registration procedure is handled by the European Medicines Evaluation Agency (EMA). Authorization through the central registration procedure is immediately valid in all EU member countries. The decentralized procedure relies on the principle of mutual recognition. After registration has been obtained in a member country under the centralized procedure, application may be made for registration in one or more other member countries via the decentralized procedure (21).

The majority of pharmaceuticals are distributed through wholesalers to retail pharmacies, with large pharmacy chains now dominating the market. There are approximately 11,000 community pharmacies in the United Kingdom (21). In recent years, pharmacy services are increasingly available in supermarkets at the expense of local independent pharmacies.

Total expenditure on pharmaceuticals in the United Kingdom amounted to approximately 8650 million pounds in 1999, accounting for approximately 17% of the total health expenditure (21). The NHS covers prescription drugs. However, the government does not reimburse for over-the-counter (OTC) products. The Department of Health indirectly controls pharmaceutical prices. Because the price control scheme is related to profit control, rather than to the prices of individual products, pharmaceuticals are relatively free-priced in the United Kingdom. The government operates a negative list for products that are not reimbursable. The cost of most licensed prescription products is fully reimbursed. However, cost constraints and prescribing budgets mean that GPs will often prescribe a generic when one is available. As a result, new prescription drugs usually have a slower penetration rate in the United Kingdom than in the United States. The recently introduced National Institute for Clinical Excellence (NICE) will add more barriers to the introduction of new pharmaceutical products in the United Kingdom.

National Institute for Clinical Excellence

Funded by the government, the National Institute for Clinical Excellence (NICE) was set up as a Special Health Authority in the United Kingdom in 1999 and, as such, it is a part of the National Health Service (NHS). It was set up to "provide the NHS [patients, health professionals, and the public] with authoritative, robust and reliable guidance on current best practice." Its key functions are "to appraise the clinical benefits and the costs of those [health care] interventions and to make recommendations." Guidance is issued from each appraisal based on the clinical benefits, cost-effectiveness, and total economic impact on the

National Health Service. The government does not have to adhere to the recommendations by the NICE in its guidance and financial payment to health care providers. However, many believe that a negative recommendation from the NICE will have a detrimental impact on the pricing, reimbursement, and sales of the appraised product not only in the United Kingdom but also throughout Europe, Australia, and Canada.

The guidance covers both individual health technologies (including medicines, medical devices, diagnostic techniques, procedures, and health promotion) and the clinical management of specific conditions. The Institute may recommend a technology for general use, for specific indications, or for defined subgroups of patients. Based on the appraisal, a therapeutic intervention (e.g., drug) will be classified into one of three categories: category A, routine use in the NHS; category B, further trials needed; and category C, not recommended for routine use in the NHS.

The NICE has a board reflecting a range of expertise including the clinical professions, patients and user groups, NHS managers, and research bodies. The Board ensures that the NICE conducts its business on behalf of the NHS in the most effective manner. Details of the appraisal process and membership of the Appraisals Committee are available on the NICE Web site (www.nice.org.uk). Because the NICE was new at the time of completion of this article, its impact on the pharmaceutical industry is still not clear.

Germany

Organization

With a population of approximately 82 million in 1998 and a GDP per capita of more than \$26,000, Germany is one of the world's largest economies and health care markets. The population enjoys a generally good standard of health with a high degree of public awareness about health-related issues. Life expectancy in Germany is among the highest in the world. In 1997, the life expectancy for males was 74 years and for females 80. Approximately 15.8% of the population were over 65 years in 1997, and it has been projected that by 2020, the number of German inhabitants aged over 60 years will be 28.2% (22).

In 1997, health expenditures in Germany totaled \$298 billion, equal to 14.2% of the GDP. The health care system in Germany is decentralized, and health care expenditures are covered by a variety of sources/payers. The statutory insurance system (GKV) represents the biggest proportion of the total care coverage (for almost 50%). Employers, government budget, private households, private insurance, retirement insurance, and accident insurance cover the

remaining 50% of the health care expenditures. The largest spending sector is hospital expenditure, representing 34.3% of the total GKV health care expenditures (22).

The federal government has little executive responsibility for the provision of health care in Germany. Its primary responsibility is to provide a regulatory framework within which the individual Länder have to operate. The health ministries of the individual Länder are responsible for implementing the federal legislation, enacting their own legislation, supervising subordinate authorities and the medical profession, hospital planning, and regional administration.

Hospitals in Germany can be classified into three major categories based on ownership: public, nonprofit, and private. In 1997, the public sector operated approximately 40% of general hospitals, and nonprofit organizations operated another 40%. However, the number of privately owned facilities has been increasing steadily over the past decade.

The number of practicing doctors has risen steadily for the past 10 years. More than 70% of the practicing doctors are specialists, with general medicine as the largest specialty. Fewer than 30% of doctors practice without any specialty.

Pharmaceuticals

Germany is a reference member of the EU pharmaceutical registration system. The European Medicines Evaluation Agency (EMA) handles the centralized registration and the decentralized registration procedures in individual countries. After marketing authorization of a product with a new active substance has been granted in one country, the mutual recognition procedure is compulsory in other member countries. The mutual recognition procedure is also compulsory for line extensions and generic products. Marketing authorization approvals in Germany are valid for 5 years and renewable thereafter in 5 year periods.

Germany is the home of some major multinational pharmaceutical companies such as Aventis, BASF, Bayer, Boehringer Ingelheim, Merck KGaA, and Schering AG. VFA is the research-based manufacturers' association, whereas the Bundesverband der Pharmazeutischen Industrie (BPI) represents small and medium-sized companies. Because North America is the largest pharmaceutical market in the world, many of the VFA pharmaceutical companies locate their key operations in the United States. Exports to Western European countries represent a major source of income for many of the German pharmaceutical companies.

The pharmaceutical market in Germany is one of the largest in the world. Based on drug use per capita, Germany is second only to Japan in the consumption of pharmaceuticals. The principal distribution channels for pharmaceuticals in Germany are public retail pharmacies and hospital

pharmacies. In 1998, there were 47,322 pharmacists in Germany, equal to 0.6 pharmacists per thousand population (22). Public (retail) pharmacies employed 96% of all pharmacists in 1998 and they obtained their supplies primarily from wholesalers. Prescribed drugs, including both branded and generic products, can only be dispensed in a pharmacy with a doctor's prescription. The generics market in Germany is one of the largest and fastest-growing in Western Europe, representing approximately one-third of the European generics markets. OTC products can be divided into three overlapping categories: prescription OTC medicines, nonprescription OTC medicines, and freely available OTC products that can be sold freely through all retail outlets such as health food stores, supermarkets, and other retail outlets.

Mexico

Organization

Mexico is a federal republic of 31 states and a federal district. The population was officially estimated to be 97.7 million in 1997. GDP per capita was estimated at approximately US \$4400 in 1998. As a developing nation, communicable diseases are still one of the major causes of mortality, although chronic and degenerative diseases have become the leading cause of death during the past decade.

One of the major challenges for the government is to address the inadequacies of the Mexican health care system. Approximately 10 million people have virtually no access to regular basic health care services, and another 20 million people have less than adequate access. In 1996, the total health care expenditure in Mexico was equivalent to approximately 4.6% of GDP. Spending by the public sector accounted for approximately 60% in 1996 (23).

There are three sectors in the Mexican health care system: public, social security, and private. The public sector is primarily directed and operated by the Secretariat of Health. The public sector of health services is under the Secretariat of Health and is coordinated by over 200 health districts. The Federal District Department provides health care services to some 3.2 million people in Mexico City. The Mexican Social Security Institute (IMSS) Solidarity program covers another 10 million people in rural areas.

The social security system covers health services for government employees, managed by the Social Insurance Institute of State Employees (ISSSTE), and for private-sector workers, managed by the Mexican Social Security Institute (IMSS). The two agencies operate their own networks of hospitals and clinics and provide similar benefits. Some other smaller social security agencies exist, providing medical services for special groups such as the army, navy, and state oil company personnel.

The private (commercial) sector includes private hospitals, doctor's offices, and practitioners of traditional medicine. Charity organizations such as the Red Cross also play a role in the Mexican health care system.

Pharmaceuticals

The regulatory authority in Mexico is the Dirección General de Control de Insumos para la Salud (DIGECIS). The Health Secretariat issues pharmaceutical registration. Safety and efficacy must be proven by phase III clinical trials in Mexico to register drugs that are new to the Mexican market. All major pharmacopoeia (*International Pharmacopoeia*, *US Pharmacopoeia*, *British Pharmacopoeia*, *French Pharmacopoeia*, *Swiss Pharmacopoeia*, *European Pharmacopoeia*, and *Japanese Pharmacopoeia*) are acceptable in Mexico.

Most domestic producers in Mexico are wholly owned or licensed subsidiaries of multinational pharmaceutical firms. Exports have been growing fast, with other Latin American countries as the major destination markets. However, the United States is the major supplier of pharmaceutical imports in Mexico.

Pharmaceuticals in Mexico are subject to government price control. The private sector accounts for approximately 85% of the pharmaceutical market. Prescription drugs account for the majority of the pharmaceutical market, with antibiotics as one of the largest classes. Because the use of generics is still a relatively new phenomenon, most of the prescribed pharmaceuticals are branded products. OTC products represent approximately one-fifth of the total pharmaceuticals market.

SUMMARY

As presented, these six representative countries use vastly different organizations, financing mechanisms, goals, and provision structures. In fact, few systems around the world are identical because the systems represent the values and priorities and political as well as economic leanings and traditions of that country. If there were one perfect system, we would be seeing migration toward that model. However, because this is not the case, it is reasonable to assume that most of the various systems encountered around the world are at least satisfactory in their foundations and macrolevel characteristics, even if some of the operating details are not always popular (24).

The world is full of interesting additional approaches that a serious student of this subject might wish to explore further. Some of these include the "need clause" used in Norway, where, for example, their FDA had the authority

to refuse to accept and review a new drug because Norway already had six benzodiazepines on the market. The FDA deemed that sufficient unless the sponsoring company knew of a new indication or other therapeutic breakthrough from its use. The Swedes bought all of the then-existing community pharmacies in the country in 1970 to rationalize distribution, and service level and to create a monopsonistic body for negotiating with manufacturers in price-setting. The French and others place new drugs into one of several reimbursement categories. Clearly, life-saving drugs are put in the 100% reimbursement (to the patient) category. Most others strive for the 70% reimbursement category; however, if the manufacturer cannot agree on a price satisfactory to the Social Security agency, the product will be placed in a lower reimbursement category, effectively hampering its market success. This is a powerful bargaining chip for the government to contain drug prices.

It will be interesting to watch the future in this area to see how medications previously requiring a doctor's prescription that move to OTC status are handled, and how nutraceuticals, herbals, homeopathic, and naturopathic drugs, without the benefit of rigorous, randomized clinical trial or outcome data are handled as well. Similarly, we can be certain that there will be excitement galore when the nations in Central America and the Middle East decide to control pharmaceuticals and to end the practice of lay-person purchases of virtually any product without the benefit of a physician's order. Separation of pharmacy and physician functions will occur in the Far East in the not too distant future, causing even more excitement or grief.

If logic dictates, we should expect to see in the future a trend to offer incentives for prescribers who use the most cost-beneficial products (bonuses) and disincentives for patients (reimbursement level co-payment differences) and physicians when less than optimal choices are made. Irrespective of whatever does actually occur, it will be most interesting to observe.

Headspace Oxygen Analysis in Pharmaceutical Products

Allen C. Templeton

Robert A. Reed

Merck & Co., Inc., West Point, Pennsylvania, U.S.A.

INTRODUCTION

Oxidative chemical degradation of drug substances in pharmaceutical formulations is well documented.^[1] Although exact mechanistic details on what governs the promotion of reactions between drug substances (RH) and molecular oxygen in pharmaceutical formulations is not fully understood, it is generally thought that such reactions fall under the category of autoxidation processes^[1,2]:

Initiation $\text{RH} \rightarrow \text{R}\cdot$

Propagation $\text{R}\cdot + \text{O}_2 \rightarrow \text{ROO}\cdot$

$\text{ROO}\cdot + \text{RH} \rightarrow \text{ROOH} + \text{R}\cdot$

Termination $\text{ROO}\cdot \rightarrow \text{Molecular products}$

Note in the above reaction scheme that molecular oxygen is involved in the propagation step of the reaction and is integral to the catalytic cycle responsible for the generation of drug substance oxidative degradation in pharmaceutical formulations.

Oxidative degradation of the active drug substance in a pharmaceutical formulation leads to a lowering of drug potency and potentially reduced product shelf life.^[2] The rate of oxidative degradation is proportional both to the structural susceptibility of the specific drug substance to auto-oxidize and storage (reaction) conditions such as temperature, humidity, oxygen concentration, and time. Other deleterious effects of oxidative processes that have been noted include product discoloration, changes in dissolution rate/profile, precipitation, and the generation of foul odors and flavors.^[1] Most importantly, oxidative degradation products generated in the final pharmaceutical product upon storage may also have adverse pharmacological properties, including those related to toxicity or adverse side effects.

In addition to oxidative degradation of the finished product upon shelf storage, drug oxidation during the manufacturing process can also pose significant challenges for readily oxidized drug substances. The effects are especially pronounced for formulations where

manufacturing unit operations are performed in solutions and/or suspensions. In these cases, care may be required to minimize or eliminate exposure to oxygen during key processing steps. Inert gas purges to lower solution oxygen levels and inert blanketing of process vessels have long been employed in parenteral manufacturing processes. Besides purging at key manufacturing steps, e.g., during drug compounding and holding in solution prior to lyophilization, packaging with an inert blanket over the final product has also been employed for parenteral formulations susceptible to oxidation. By removing from the package one of the two key reactants in the autoxidation cycle, important gains can be made in product shelf life and the quality of the product reaching the consumer. Packaging oxygen-sensitive products under an inert atmosphere, often termed modified atmosphere packaging (MAP), is a process widely adopted to increase the shelf life of other oxygen-sensitive commercial products, including foodstuffs and medical devices. While MAP has taken hold in the parenteral arm of the pharmaceutical industry, there are relatively few examples of solid dosage forms that are packaged under reduced oxygen levels.

“Smart” packaging approaches like MAP may allow for the commercial development of oral formulations with drug compounds particularly prone to oxidation and thus allow for the availability of critical therapeutic agents in a high quality, stable, and convenient dosage form. The development cycle time of such compounds could also improve, in that, efforts to stabilize the compound by both formulation and packaging can be successfully integrated. Thus, MAP implementation for solid dosage forms is clearly on the horizon. Keys to successfully deploy MAP for any oxygen-sensitive product are: 1) utilization of packaging that presents a high barrier to oxygen permeation; 2) incorporation of an inert gas flushing step compatible with the speed of current product packaging lines; 3) selection of an appropriate inert gas (e.g., argon, nitrogen, carbon dioxide, etc.); and 4) rapid means to measure residual headspace oxygen content in a variety of pharmaceutical packaging configurations—ranging from very low (tens–hundreds of μL) to relatively high volume (mL – L) packages.

ANALYTICAL APPROACHES FOR HEADSPACE MEASUREMENTS

Fast, sensitive methods for monitoring headspace oxygen levels would critically benefit MAP development and deployment in all three areas listed above, aiding in each of the phases involved with packaging R&D, manufacturing process development, and final product quality assurance. In terms of packaging R&D, robust oxygen measurement methods would allow for a real-time screening of the suitability of packaging systems (all components of a container and closure) to serve MAP packaging applications. The most obvious example of this would be the acquisition of oxygen ingress kinetics for the packaging system under both realistic and accelerated storage conditions. Experimental data could be used to develop predictive models around each critical packaging system component to support future MAP development programs. For manufacturing process development, scaling and validating a manufacturing process that allows maximum package throughput per unit time while achieving and maintaining critical threshold levels for oxygen would benefit from rapid and accurate oxygen determination in the development feedback loop. Finally, tools to provide quality assurance/control information (at-, on-, or off-line) would ensure that the oxygen content of the inert atmosphere in the packaging container headspace is below the predetermined specification for the product. An assessment of container closure integrity could also be determined using such testing, augmenting or replacing

current microbial/dye ingress measurement approaches based on sterility assessment.

The rapid and accurate determination of headspace oxygen levels in the various packaging configurations used in the pharmaceutical industry poses a number of unique analytical challenges that are beyond the capabilities of a single measurement technique. The purpose of this article is to provide a background on various measurement options available to the packaging R&D technologist or laboratory analyst in the context of pharmaceutical packaging applications. The article is organized by technique with a brief introduction to measurement principles, followed by a critical discussion of pharmaceutical packaging applications.

A REVIEW OF HEADSPACE OXYGEN ANALYSIS TECHNIQUES

Headspace Gas Chromatography (GC)

Principles of operation

When a problem arises in a pharmaceutical research laboratory that requires analysis of a headspace sample, the first tool that probably comes to mind is the tried-and-true approach of headspace GC. This is for good reason, as the literature points to a vast body of knowledge, stretching back 40 yr, on the theory and application of this methodology.^[3] While not taking away the importance

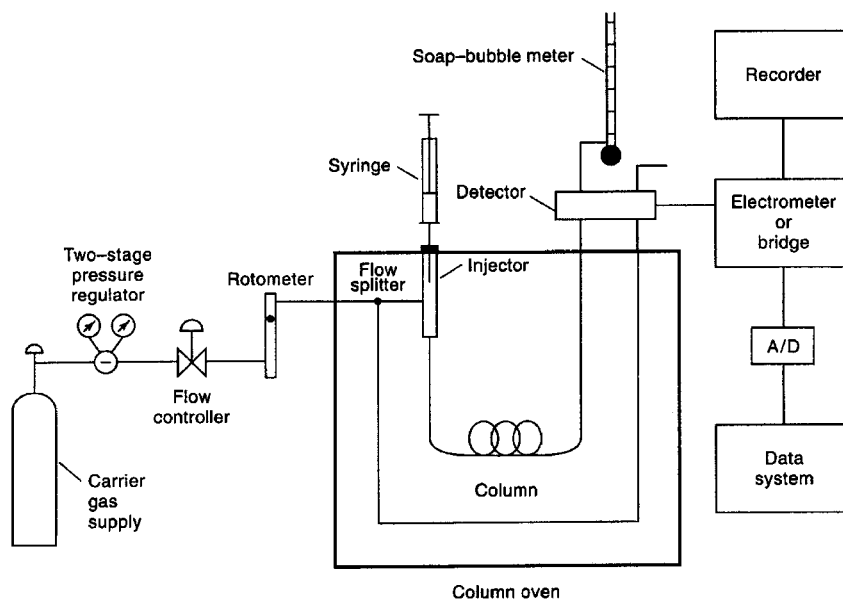

Fig. 1 A block schematic of the components that comprise a typical GC instrument. (From Ref. [12], p. 41. Copyright ©2002 Advanstar Communications Inc. Advanstar Communications Inc. retains all rights to this material.)

Headspace Oxygen Analysis in Pharmaceutical Products

3

of headspace GC as an analytical problem-solving tool, which stretches far beyond the bounds of oxygen analysis, a number of problems exist where other techniques can provide similar or better results for specific headspace analytes, often in a more timely fashion. The following description of headspace GC is only intended as a cursory overview; refer the substantive literature of the field for greater detail on the subject.^[3]

GC is inherently a technique for the study of volatile compounds. Fig. 1 shows a block schematic of the components that comprise a typical GC instrument equipped with split injection port and capillary column. For headspace sampling, a gaseous sample is introduced by injection into an inert moving gas stream called the mobile phase or carrier gas.

The mobile phase transports the sample onto a stationary phase where the components of the sample are separated by means of selective partitioning between stationary and mobile phases. The time referred to as retention time (t_r), which elapses between sample introduction and when peaks appear at the detector, is characteristic of the properties of the analyte molecules. The area of the respective peaks as they appear in the resultant chromatogram is proportional to the analyte concentration in the sample, as related by a measurable response factor. For the analysis of headspace oxygen in pharmaceutical applications, a sample of headspace (tens of μL) is removed from a package either by withdrawing a portion of sample using a gas-tight syringe or by using

the GC autosampler to pressurize the container with mobile phase to displace an aliquot of sample. Performing the experiment in either manner would mean operation in what is referred to as the static mode of headspace sampling, wherein the aim is to sample the equilibrium contents of a sample headspace at a given instance.

Fig. 2 shows an example chromatogram of lab air illustrating the determination of headspace oxygen using a megabore capillary column with thermal conductivity detection. As in any type of chromatographic analysis, selection of the appropriate column to achieve separation of the sample gas mixture into its various components is pivotal. In this case, a commercially available thin-film porous layer open tubular (PLOT) capillary column consisting of a fused silica capillary tube coated with a homogeneous 50- μm thick zeolite molecular sieve (5/pore size) film was used to separate oxygen from argon and nitrogen in an air sample during a 10-min analysis. The mode of separation is based on the size of the analyte molecule or atom, and retention time is as follows: Nitrogen > Oxygen > Argon. The net area and percent area of oxygen are determined from the following equations:

$$\text{Area}_{\text{Net},x} = \frac{(\lambda_{\text{He}} - \lambda_x)}{\lambda_{\text{He}}} \times \text{Area}_{\text{Raw},x}$$

$$\text{Area}_{\text{Net},x} \% = \frac{\text{Area}_{\text{Net},x}}{(\text{Area}_{\text{Net},\text{Argon}} + \text{Area}_{\text{Net},\text{Nitrogen}} + \text{Area}_{\text{Net},\text{Oxygen}})} \times 100\%$$

Fig. 2 An example chromatogram illustrating the determination of headspace oxygen by GC using a PLOT molecular sieve column with thermal conductivity detection. Chromatographic conditions were carrier gas: helium (2 mL min^{-1}); oven temperature: 26°C ; inlet: 160°C , split mode, 10:1 split ratio, split flow of 20 mL min^{-1} ; injector: 160°C ; run time: 10 min; TCD detector: 160°C . (From Ref. [12], p. 41. Copyright ©2002 Advanstar Communications Inc. Advanstar Communications Inc. retains all rights to this material.)

where x is argon, nitrogen, or oxygen, $\text{Area}_{\text{Raw},x}$ the raw peak area of x ($\mu\text{V sec}$), $\text{Area}_{\text{Net},x}$ the net peak area of x after conversion, λ_{He} the conductivity of helium ($154.6 \text{ W m}^{-1} \text{ K}^{-1}$), and λ_x the conductivity of argon ($17.8 \text{ W m}^{-1} \text{ K}^{-1}$), nitrogen ($25.9 \text{ W m}^{-1} \text{ K}^{-1}$)*, or oxygen ($26.2 \text{ W m}^{-1} \text{ K}^{-1}$)*.

A potential drawback of GC or any technique requiring use of a syringe for sample injection is the potential for contamination. Contamination can result from: 1) leakage of the package during sample removal; 2) syringe leakage during sample transport from package to instrument; 3) septum port leakage during sample introduction; and/or 4) contamination from residual air remaining in the syringe barrel. Residual air contamination from syringe barrel leads to a direct correlation between contamination and syringe barrel volume.

Applications

The utilization of headspace GC to analyze oxygen in pharmaceutical packages and samples offers several advantages, such as the widespread availability of instruments and user familiarity. For sample containers of appropriate dimensions, the autosampling capability of commercial headspace GCs makes the instrument particularly appealing for analyzing samples en masse. GC autosampler vial dimensions are not typically consistent with common pharmaceutical package sizes. Thus, the utility of the autosampler is typically limited to either a few samples of appropriate dimension or samples that can be transferred to headspace autosampling vials; the latter would defeat the purposes of many investigations. Withdrawing and injecting samples manually using a gas-tight syringe can pose various problems in addition to those noted above; for example, when working with samples that are under vacuum, pressure equalization with ambient air can lead to sample dilution and erroneously large values for oxygen. Thus, care must be employed to use a gas-tight locking syringe and institute appropriate controls, as described in the previous discussion. Moreover, care must also be taken when removing sample from packages without introducing ambient atmospheric leakage during the sampling process; application of a self-adhesive rubber septum prior to puncturing the sample is usually sufficient as a preventative measure when puncturing through aluminum foil (e.g., foil induction sealed HDPE bottles). Samples sealed with rubber stoppers (e.g., lvo vials) usually provide an adequate barrier to leakage during sampling. Sampling is a problem common to all destructive headspace oxygen analysis methods and points out the difficulties in trying to quantitatively measure small quantities of a gaseous analyte without contamination with air. Despite problems with sample removal, the low absolute sample volume

requirements (tens of μLs) make static headspace GC attractive and potentially useful for pharmaceutical packages and samples of all types/sizes. Following sample introduction, the major limitation of the technique for analysis of oxygen is the requirement of a relatively lengthy separation step (few minutes at best) to be oxygen selective, coupled with needed assessment of appropriate standards and demonstration of system suitability throughout analysis of a sample set. Lastly, although traditionally a GC instrument has a large footprint that would make at-line work unfeasible, recent commercial development of portable GC units (sometimes termed μGCs) is beginning to make at-line sampling more feasible.

μGC systems operate under the same principles as do conventional headspace GC analyzers. The key difference is scale, and scale translates into sample volume requirements. The instrument typically is comprised of miniaturized injector, column, and detector all mounted in a single module or channel. The sample is introduced through the inlet via an internal diaphragm pump connected to the end of the module. Due to the extremely low volume of the sample tubing and microscale nature of the instrumentation components, analysis volumes can be of the order of tens of microliters and analysis times less than 60 sec. Thus, the analysis time disadvantages of conventional headspace GCs are overcome with a μGC . An additional significant advantage with μGCs is that typical systems are two channel and allow for the simultaneous determination of two headspace analytes (e.g., oxygen and moisture).

Electrochemical Methods

Principles of operation

The use of electrochemical methods for oxygen analysis also has long historical precedence both from a scientific and commercial perspective. The basis of operation of most commercial electrochemical headspace oxygen analyzers is a solid-state zirconium oxide ion-selective electrode.^[4] In this sort of sensor, oxygen ions are able to migrate into the defect sites in the ceramic lattice structure of zirconia at elevated temperatures ($>400^\circ\text{C}$). As has been known since the time of Nernst (1899), when gases of differing concentrations reside on opposite sides of an electrode membrane, a measurable potential (E') difference is generated. If one side of the membrane is exposed to gas of reference oxygen concentration $[\text{O}_2]_{\text{REF}}$, then the potential generated in the presence of a gas of unknown oxygen concentration $[\text{O}_2]_{\text{UNK}}$ is proportional to the difference in oxygen concentration across the membrane, as given by the Nernst equation^[4]:

$$E = \frac{RT}{nF} \ln \frac{[\text{O}_2]_{\text{REF}}}{[\text{O}_2]_{\text{UNK}}}$$

where E is the potential (V), R the gas constant (J K^{-1}), T the temperature (K), n the number of electrons transferred,^[4] and F the Faraday's constant (J mV^{-1}).

In practice, the measurement procedure involves puncturing the package and removing (usually with a small diaphragm pump) 2 mL–4 mL of headspace for purging and subsequent analysis in a small cell containing the electrode. The analysis is rapid, typically of the order of 5 sec. Importantly, the measurement is not adversely affected by humidity, but the sensor can be damaged if inadvertently exposed to liquid samples. Commercial instruments, which allow the simultaneous measurement of oxygen and carbon dioxide levels in headspace samples, are available with sampling accessories for a variety of package containers and sample types (e.g., aluminum cans, beer bottles). There also exist commercial electrochemical oxygen analysis techniques that are based on the direct reduction of oxygen at a planar gold electrode (Clark techniques or modifications thereof). The latter may prove useful for specific headspace oxygen analysis problems, such as monitoring oxygen during a processing step.

Applications

The sample volume requirements of electrochemical methods limit the use of the analysis approach to pharmaceutical packages and sample configurations of larger dimensions containing ≥ 2 mL headspace volume, such as HDPE bottles, glass vials, and blister packages (individual blisters) of sufficient volume. The rugged character of such instruments and their ease of use make the technique particularly suited for use in a manufacturing setting.

Frequency Modulation Spectroscopy (FMS)

Principle of operation

Recently commercialized for package inspection applications, FMS is a high-sensitivity laser absorption technique that is useful for nondestructive monitoring of gas concentrations in optically transparent containers.^[5–8] Oxygen absorbs near infrared (NIR) light in a band of rotational transitions centered at 762 nm. Oxygen absorbance measurements, at this wavelength on typical NIR spectrometers that use incoherent white light sources, lack the sensitivity to provide a useful measure of headspace oxygen levels due to low frequency lamp intensity fluctuations. However, the measurement signal-to-noise (S/N) can be vastly improved (100–10,000X) by utilizing laser light sources and frequency modulation detection techniques. When a tunable diode laser is modulated using a radio frequency oscillator, the detection bandwidth can be shifted to high frequency where intensity

fluctuations, inherent to low frequency measurements, are minimized.

The measurement is conducted by frequency modulating a diode laser by superimposing a radio frequency oscillation, Ω , onto the diode injection current. The spectral output of a frequency modulated diode laser, shown at the top of Fig. 3, consists of a carrier frequency, ω_c and side band frequencies, $\omega_c \pm \Omega$. When the laser is scanned through the wavelength of oxygen absorbance, the amount of light absorption, which is proportional to the gas concentration, is “written” into the side band frequencies by recording the difference in absorption between the two sidebands. The differential absorption information is recovered using phase sensitive detection techniques. The demodulated absorption line shape is shown in Fig. 4. The amount of light absorbed is directly proportional to oxygen concentration. The gas density, n , is related to the peak-to-peak signal amplitude, ΔI , by Beer's law, which for a weakly absorbing molecule, is given by:

$$n = (\Delta I \pi / I_0 S x) \text{cm}^{-3}$$

where ΔI is the change in intensity of light after passing through the container (W cm^{-2}), Γ the full width at half maximum of the absorption signal (cm^{-1}), π a constant, I_0 the incident laser intensity (W cm^{-2}), S the integrated absorption cross section ($\text{cm}^2 \text{cm}^{-1}$), and x the container diameter (cm). The measured density in a sample vial is referenced to a standard and displayed as a concentration (%).

Applications

Application of the technique is limited to headspace monitoring in packages, which are optically transparent (glass vials, ampoules, bottles—including colored glassware such as amber) or translucent (LDPE, but not HDPE packages). Other containers with various optical densities and corresponding transmittance properties could also be potentially sampled, but would need to be evaluated on a case-by-case basis. Packages are inserted into a sample holder that can be customized for cell volumes of ~ 1 mL–100 mL, which typically present cell pathlengths of 1 cm–3 cm.

The principal advantage of the method is that it can nondestructively analyze oxygen contents within sealed containers without change to the sample. Thus, a single package can be used to study oxygen concentration profiles at periodic intervals and under various storage conditions without the need to destructively insert a probe or remove the headspace contents for analysis. The value of this cannot be overstated in terms of absolute sample requirements, sample preparation time, and

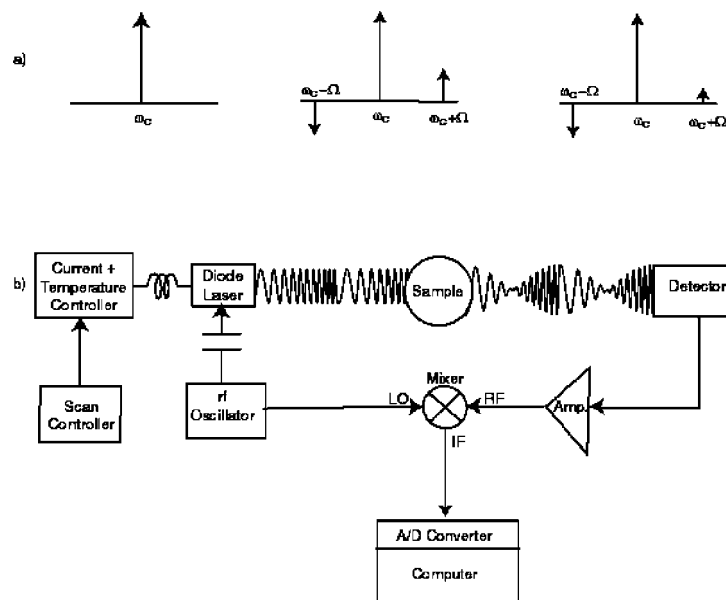

Fig. 3 a) Frequency and intensity profile of a diode laser beam, from left to right: unmodulated, modulated with no absorption, and modulated with absorption by the upper sideband. b) Schematic diagram of an instrument for FMS. The frequency modulated diode laser output is converted to an amplitude modulation after passing through a gas sample, which absorbs at a particular wavelength. The amplitude modulation is proportional to gas concentration and can be phase sensitively detected and related to oxygen concentration. (From Ref. [12], p. 41. Copyright ©2002 Advanstar Communications Inc. Advanstar Communications Inc. retains all rights to this material.)

sample-to-sample variability. From a quality assurance perspective, substantial cost-savings could also be realized from a nondestructive analysis approach. Development of on-line instrumentation would also be of significant value

for performing 100% inspection of the headspace oxygen contents of some parenteral packages.

Fluorescence Quenching Methods

Principles of operation

Oxygen sensing technologies based on luminescence quenching are also a relatively new commercial development and the scientific underpinnings for their operation is described extensively in a recent review article.^[9] The purpose of this discussion will be to briefly introduce this oxygen measurement technology; the reader is referred to more specialized literature for more details. In one commercial configuration (schematic shown in Fig. 5), fluorescence is used to measure the partial pressure of oxygen by using a bifurcated optical fiber to transmit an excitation source from a blue/green LED ($\lambda_{\max} = 470$ nm) to a thin-film coating applied to the tip of the fiber. A ruthenium complex dispersed in the thin film is excited and produces a fluorescence emission maximum at 600 nm that is collected at the tip and carried back to a CCD detector. The intensity of fluorescence observed is inversely proportional to the amount of oxygen in a liquid or gaseous sample.

Luminescence quenching sensors can be explained by the following processes, where M represents

Fig. 4 Frequency modulation signals from oxygen absorption. The peak-to-peak amplitude of each spectra is proportional to oxygen concentration (noted to the right of each scan). (From Ref. [12], p. 41. Copyright ©2002 Advanstar Communications Inc. Advanstar Communications Inc. retains all rights to this material.)

Fig. 5 Schematic of headspace oxygen analyzer based on fluorescence quenching. (From Ref. [12], p. 41. Copyright ©2002 Advanstar Communications Inc. Advanstar Communications Inc. retains all rights to this material.)

the luminescing molecule and Q is a quencher:

Photon Absorption (I_a) $M + h\nu \rightarrow M^*$

Luminescence (k_r) $M^* \rightarrow M + h\nu$

Nonradiative decay (k_{nr}) $M^* \rightarrow M + \Delta$

Dynamic Quenching (k_q) $M^* + Q \rightarrow M + Q^*$

Quenchers act by depleting the excited-state population (M^*), thus lowering the intensity of luminescent emission or shortening decay time. In the case of commercial oxygen sensors, M is a fluorescent ruthenium dye whose fluorescence intensity is quenched by oxygen in a manner commonly referred to as “dynamic fluorescence quenching.” In terms of the process described above, a collision of an oxygen molecule (Q) with the fluorophore in its excited state (M^*) leads to a nonradiative energy transfer and a loss of fluorescence intensity.

The amount of fluorescence intensity quenching can be quantitatively related to the partial pressure of oxygen in a sample from the simplified Stern-Volmer equation^[9]:

$$I_0/I = 1 + Kp_{O_2}$$

where I is the quenched fluorescence signal intensity, I_0 the unquenched fluorescence signal intensity, K the quenching constant that is related to particular fluorophore employed as M, and p_{O_2} the oxygen partial pressure.

An expanded version of the Stern-Volmer equation containing a factorial expansion of these same terms can also be employed to relate I_0 to oxygen levels in a more exact manner. Standard operation includes, at minimum, a daily calibration at a number of oxygen concentrations (at a fixed pressure and temperature) and use of the measured

calibration coefficients to determine the concentration of oxygen in an unknown sample.

Frequent recalibration is necessary since the sensors tend to degrade under normal operating conditions. This is particularly true of new sensors, which may require “burn in” over a few hours operation before stable operation is achieved. Analyses are accomplished by inserting a needle probe into a sample vial and waiting a fixed time for equilibration of the sensor to the headspace environment. The equilibration time is a function of the chemical composition of the protective overcoat applied to the sensor tip to exclude ambient light (a Teflon[®] AF coating was used in the present study). It is well known^[9] that the accuracy of fluorescence quenching is limited by resolution (random noise), deviations from the Stern-Volmer relationship, and calibration error. All these factors can promote measurement inaccuracy.

Applications

Fluorescence quenching sensors do not actually consume headspace oxygen and thus can be miniaturized for use on very small volume samples. However, the technique is still destructive as the tip of a 300 μm probe must still be used to puncture the package and come in contact with the relevant headspace, allowing an effective smallest volume that can be probed of about 100 μL . Some attractions of the technique include: 1) rapid response times (5 sec–2 min) that are limited to the time required for equilibrium to be reached between oxygen in the sample headspace and the sensing film by way of diffusion through the protective overcoat; 2) very low sample volume requirements ($\sim 100 \mu\text{L}$) that are limited only by

the contact dimensions of the probe; and 3) low cost and small instrument footprint. The low sample volume requirement makes it one of the two instruments capable (the other is headspace GC) of rapidly measuring oxygen levels in individual blister cavities of typical dimensions employed in pharmaceutical packaging. The small size and easy setup also make this instrument very attractive from a portability perspective for use in potential at-line packaging measurements. Fluorescence quenching instruments are also available in multichannel configurations that allow for the simultaneous measurement of several samples and the data logging component of the software allows for programmed measurements at fixed time intervals.

The various limitations of the method should also be noted. Care must be taken to calibrate across the intended measurement temperature range of samples, as fluorescence quenching levels change as a function of temperature. Temperature effects the measurement by impacting fluorescence decay time and the collisional frequency of oxygen with the fluorophore. Requirements to maintain the sample at $\pm 1^\circ\text{C}$ or to concurrently measure temperature while conducting the measurement curtail the practical utility of the approach. Experience in our own lab has also pointed out a need to consistently use longer signal integration times over the life of any given probe to achieve sufficient signal intensities over background noise. The decreased response factor observed could be due to changes in the ruthenium dye (e.g., degradation) over time. Higher signal intensities and/or

lower noise levels are desirable because the S/N ratio is proportional to the square root of integration time. Moreover, as can be seen from the Stern-Volmer equation, the rate of change of signal intensity with quenching will be largest at lower oxygen levels. Further development of the instrumentation for oxygen-specific measurements would greatly benefit the overall utility of the technique.

Quadrupole Mass Spectrometric Analyzers

Principles of operation

Quadrupole mass analyzers are by far the most common type of mass spectrometer in use today and the literature on these type of analyzers is extensive.^[10,11] Quadrupole mass analyzers are often thought of as mass filters because they can be tuned to transmit ions of a narrow range of mass/charge (m/z) ratios. Fig. 6 shows a generalized block schematic of a quadrupole mass spectrometer. A typical quadrupole instrument separates ions with different masses by application of a combination of static and radio frequency electric fields to four cylindrical rods. A headspace gas sample is introduced at an inlet and fed into an ion source where electrons are emitted from a filament and ionize the sample gas. The sample ions are then accelerated in an electrical field and are injected into the opening at the center of the rods. In the simplest systems, one pair of rods is connected and attached to the positive terminal of a d.c. power source, the other connected pair is

Fig. 6 Block schematic of a quadrupole mass spectrometer. (From Ref. [12], p. 41. Copyright ©2002 Advanstar Communications Inc. Advanstar Communications Inc. retains all rights to this material.)

attached to the negative end of the same source. A variable rf field with phase differences of 180° is also applied to each connected pair of rods with ac power supply. In order for an ion to travel through the quadrupole to the detector, the ion must have a stable trajectory in the presence of these applied voltages and electric field, as described by the so-called Mathieu equations of motion for ions in an electric field. For the purpose of this brief discussion, the application of a particular set of voltages to the rods allows mass filtering and the transmission of a band of ions having a limited range of m/z values. This is usually accomplished by scanning the rf voltage and d.c. voltages from zero to a predetermined maximum value while maintaining a fixed ratio. In this manner, a mass spectrum of analyte ions reaching the detector can be recorded at a Faraday cup detector.

Applications

The application of quadrupole mass analyzers in a residual gas analysis (RGA) mode has long precedence in the semiconductor industry, where residual contaminant gas levels in various ultrahigh vacuum chambers must be monitored and controlled. The principal advantage of using quadrupole mass spectrometry for pharmaceutical applications lies in the fact that many analytes can be simultaneously monitored and quantitated (2–300 m/z) using a single injection of headspace sample. Like other destructive techniques, the largest drawback for the instrumentation is sample introduction. A number of sample introduction strategies are currently under exploration to address this issue and improve the utility of the approach. The technique would likely be useful in process monitoring applications where the detailed contents of an inert gas blanket beyond that of simple oxygen levels are required.

A COMPARISON OF TECHNIQUES

The key to matching up a technique with a specific application is to evaluate the type of information desired, instrumentation availability, and the type of packaging configuration or sample under exploration. In MAP development, the studies may range from research into the oxygen permeability properties of various packaging systems, packaging system selection, process development and implementation to quality assurance. In the evaluation of various packaging systems, the questions may be more directed toward understanding the rates of oxygen ingress (or consumption) going from very low levels ($<1\%$ oxygen) to ambient oxygen concentrations. The types of tools used in the research laboratory setting should be re-evaluated when placed into a manufacturing setting for

process development and implementation. Lastly, in a QA/QC setting, other considerations such as long-term method robustness, stability, ease of calibration and use, oxygen levels to be routinely analyzed, and other practical considerations will help guide tool selection. The examination of tool selection criteria in the forthcoming discussion will be guided by: 1) performance considerations; 2) other relevant technique attributes; and 3) the type of package under consideration.

A recent research article provided a comparison of the techniques.^[12] Key findings from this study are summarized below:

(a) *Linearity*. All the techniques reviewed provide measurements with good linearity across the measurement range 0.00%–20.0%, all displaying $R^2 \geq 0.99$.

(b) *Accuracy*. Generally speaking, for most MAP programs the aim will be to reduce oxygen values from ambient to a predetermined specified level. Often, the measurement technique may not be required to give the absolute oxygen level in the container, but rather to demonstrate sufficient accuracy as to indicate that the oxygen content of the package is below the target threshold, thus serving as a limit test. Thus, the importance of the measurement technique to measure at lower levels (e.g., $<5\%$) is more important than capabilities at higher levels. In the study noted, the performance of the techniques was examined by comparing the absolute differences observed between theory and experiment for a low level oxygen standard (0.00%). The degree of deviation (from least to greatest) observed between predicted and observation for low oxygen level standards followed the trend:

Quad MS < Electrochemical < FMS < μ GC < GC

< Fluorescence Quenching.

(c) *Limit of Quantitation*. The lower limits of quantitation can be either estimated or obtained from the vendor. For critical absolute oxygen concentration measurements at very low levels, the lower limits of quantitation should be established on the specific system under study. Sampling procedure plays a critical role in the quality of the data for oxygen levels below 2% and limits the accuracy of the data.

Knowing the performance limitations of a particular instrument is key for interpreting the results obtained from a series of measurements. As discussed next, other considerations beyond performance also have bearing on technique selection. Table 1 attempts to summarize these additional points to consider when matching the analytical requirement to a headspace oxygen analysis tool. Considerations described here include analysis time, ease of calibration/use, commercial availability, expense,

Table 1 Summary of some of the attributes of various headspace oxygen sampling tools

Instrument	Analysis time	Ease of calibration/use ^a	Instrument availability	Expense ^b (K)	Required sample volume	Destructive
GC	Minutes	3	Commercial	40 +	10 μ L–30 μ L	Yes
μ GC	Seconds	2	Commercial	15–20	10 μ L–30 μ L	Yes
Electrochemical	Seconds	1	Commercial	4–10	1 mL–3 mL	Yes
Fluorescence quenching	Minutes	3	Commercial	2–5	None ^c	Yes
FMS	Seconds	2	Semicommercial	35–50	None ^d	No
Quad MS	Minutes	3	Semicommercial	25–50	10 μ L–30 μ L	Yes

^a 1 = easiest to calibrate and use, 2 = more difficult to calibrate and use, and 3 = most difficult to calibrate and use.^b Prices estimated are US Dollars.^c A sufficient sample volume, estimated at $\sim 100 \mu$ L, must be available so that a probe can be inserted, which makes contact with the sample.^d Instrument is nondestructive and can be used on vials in which a laser can be transmitted.

sample volume requirements, and sample introduction. As Table 1 shows, analysis times for the six techniques range from minutes (GC, fluorescence quenching, quadrupole MS) to seconds (μ GC, electrochemical methods, FMS). All the instruments are available commercially, although at various stages of development, and vary in expense from 2 to 50K (US Dollars). FMS and Quad MS are the least commercially developed of the techniques at this time and more work is needed before routine use will be possible. One highly subjective term, ease of calibration/use, is included in Table 1 and reflects the authors' judgments on the relative ease of training others to operate the equipment. Other issues such as versatility, portability, and suitability for use in a manufacturing setting are also important considerations when making a decision about which instrument to use. For example, headspace GC, μ GC, and quadrupole MS have a great number of uses beyond oxygen monitoring and there may be a desire to acquire other information simultaneously (moisture, carbon dioxide, other volatiles). The only nondestructive technique of which the authors are currently aware is FMS, which can only be used with package types that allow adequate transmittance of the instrument probe beam.

Lastly, another way to approach the decision about which tool to choose can be addressed from the perspective of which package type from which oxygen levels are desired. For the sake of brevity, only the three most common pharmaceutical packaging (plastic bottles, glass vials/ampoules, blister packages) configurations are discussed.

(a) Plastic bottles with foil induction inner seal: Plastic (e.g., HDPE) bottles with foil induction inner seals (most common are 30 mL, 75 mL, 120 mL volumes) are commonly used to package pharmaceutical products. For the rapid and accurate determination of headspace oxygen analysis in a package of this configuration, any of the six

techniques discussed in this report are applicable, with the exception of FMS. Electrochemical methods are the best suited for large volume (>2 mL) packages and display an unparalleled ease of use. These instruments also tend to be amongst the most rugged of all the instrumentation described herein and seem to be the most well-suited for use by operators with a limited amount of technical training.

(b) Glass vials and ampoules: Glass vials and ampoules are another commonly used pharmaceutical packaging configuration (especially for parenteral formulations). Any of the six techniques discussed in this report are applicable for analysis of headspace oxygen levels as long as sufficient volume is available. FMS offers considerable advantages for this package type since the approach is nondestructive. Moreover, FMS can be used in vials filled with a variety of media, including sample types such as powder that may coat the walls of the container. As long as a portion of the analysis beam is transmitted, the differential absorptive signal processing inherent to the technique can be used to yield oxygen concentration values. The potential for nondestructive, on-line 100% inspection of packaging container headspace is an intriguing possibility for the approach.

(c) Blister packages: The small volume of individual blister cavities make this the most challenging of the various pharmaceutical packages to analyze for headspace oxygen levels. The challenges are twofold: the extremely small volume available for sampling and sample removal/introduction without contamination. Amongst the instruments that are applicable for small volume measurements (headspace GC, fluorescence quenching, quadrupole MS), all suffer drawbacks as measurement tools for this purpose from a sampling perspective. While future development in this area is needed, headspace GC and μ GC appear to be most suitable at this time in that self-adhesive septa can be placed on the package backing

and a small portion of sample manually withdrawn for injection. Other viable approaches, including nondestructive techniques, are currently under exploration.

CONCLUSION

This entry has provided an introduction to the principles of six measurement approaches for analyzing the headspace oxygen levels in various pharmaceutical packages. Various performance criteria have been applied to examine the fit of each particular tool to typical pharmaceutical package types. Future research on the topic would help address better the robustness of sample introduction techniques for small volume samples and perhaps the development of sensor technologies that would allow oxygen levels to be remotely interrogated and profiled over time from a small device integrated or inserted into the package.

ACKNOWLEDGMENTS

The authors wish to thank Yieng-Hau R. Han, Rajiv Mahajan, and Rey T. Chern of Merck Research Laboratories for insightful discussion. In addition, a special thanks goes to Jim Veale and Bobby Anderson of Lighthouse Instruments, Inc. for reviewing the section on FMS.

HARMONIZATION OF PHARMACOPEIAL STANDARDS

Lee T. Grady
Jerome A. Halperin

United States Pharmacopeia, Rockville, Maryland, U.S.A.

INTRODUCTION

The USP and NF^a standards of strength, quality, purity, and packaging and labeling are recognized by the U.S. Federal Food, Drug, and Cosmetic Act and Amendments since 1906. These requirements are enforced by the Food and Drug Administration (FDA), a party in the harmonization of requirements for drugs.

Although originally founded as an organization to standardize medicines in the United States, the USP and its products and services are now known and utilized throughout the world. In today's transitional and global economy for pharmaceuticals, the USP has a strong international presence and influence. Economic forces are driving major trading parties to affiliate to reduce trade barriers. Integral to this process is harmonization of requirements, regulations, and standards governing the approval and marketing of drugs, devices, etc., by governments. The mission of the USP is to promote the public health through establishing and disseminating legally recognized standards of quality and information for the use of medicines and related articles by health care professionals, patients, and consumers.

This mission is not limited to the United States. Almost from its beginning in 1820, the USP has been aware of and part of international initiatives affecting pharmacopeial standards and their use by governments and professional organizations to control drug quality. That early commitment to internationalism has now grown to formal, on-going projects of harmonization with the pharmacopeias of Europe and Japan and agreements with pharmacopeias of Argentina, Brazil, and Mexico. International programs in drug information exist with a number of multinational organizations, foreign governments, and professional groups.

^aThroughout this article, the abbreviation USP, when used alone, signifies the United States Pharmacopeial Convention, Inc. The abbreviation *USP* in italics and followed by Roman numerals signifies a particular revision of the *United States Pharmacopeia*. The abbreviation USP–NF signifies the *United States Pharmacopeia–National Formulary*, two books in a single binding.

Harmonization is wanted strongly for the role of pharmacopeias in product registration exercises. That is, product development can proceed as is, without the later repeating of studies or testing to support registration in other than the original region. The primary beneficiaries, thus, are international companies. But harmonization has an independent value in facilitating international commerce in existing products, especially excipients.

Globalization

Twenty years ago, the vast majority of all drug substances and finished dosage forms used in the United States were prepared in the United States. For various reasons before globalization, the United States lost synthetic chemical operations due to stringent environmental requirements. Also, some manufacturing was lost because of inducements of low taxes by other governments to pharmaceutical manufacturers to relocate to their countries. Neither of these factors is the same as globalization. Globalization may be the single most important, historical *worldwide* trend at this time. The entire structure of international commerce and the allocation of capital and expertise are features of globalization. In this regard, the pharmaceutical industry is not particularly different from any other industry. Today's development of drugs or biological products may occur in the United States, Europe, or a combination of nations, and no one nation can be pointed to as to the innovator of a particular drug. Also, international companies would prefer to market the minimum number of formulations worldwide. But product registration of formulations is a very complex area, and the pharmacopeias are one evidence of the fact that different formulations may require different test methods. The end point of harmonization must be monographs that are acceptable to the registration authorities in different regions. Differences in pharmacopeial standards could be seized upon to create technical barriers to trade.

Table 1 List of Interpharmacopeial Open Conferences

Conference	Location	Date
Joint Pharmacopeial Open Conference on International Harmonization of Excipient Standards	Orlando, Florida, U.S.A.	January to February 1991
Interpharmacopeial Open Conference on Harmonization of Biotechnology-derived Products Standards	Verona, Italy	April 1993
Second Joint Pharmacopeial Open Conference on International Harmonization of Excipient Standards	St. Petersburg, Florida, U.S.A.	January to February 1994
Joint Pharmacopeial Open Conference on Sterility/Preservatives	Barcelona, Spain	February 1996
International Harmonization—General Monographs on Dosage Forms and Pharmacotechnological Test Methods	Seville, Spain	October 1998

Alternative Methods

The three regional pharmacopeias—the *USP*, the *European Pharmacopoeia (EP)*, and the *Japanese Pharmacopoeia (J)* allow an individual laboratory, able to do the official method, to validate an alternative method of analysis. The latter is chosen usually for speed, convenience, or economy but also to incorporate an existing database when a new or revised pharmacopeial method is adopted. Under those provisions, a laboratory can validate a method from another pharmacopeia, thereby avoiding duplication of routine work. In all three cases, only the official method could be used in compliance or contest. One point of harmonization is to avoid even the more remote instances of duplicative testing, in addition to international product registration.

There should be support at both the national and international community levels for pharmacopeial harmonization. There should be support both for harmonization of excipients and for harmonization of common general tests and assays. In doing so, one should prefer meaningful standards, not the lowest common denominator or the most stringent. Complicating the International Conference on Harmonization 1 was the attempt to be entirely consistent with the concept of forward harmonization.

Major support for pharmacopeial harmonization would come from increased cooperation and contribution to pharmacopeias on all the nonharmonization work. Harmonization takes away scarce resources from pharmacopeias, and there are other constituencies of the pharmacopeias to be served. This is an obvious consequence of the fact that pharmacopeial standards

apply to products already in the marketplace, both brand name and generic.

Harmonization has three essential values. The first is the facilitation of international commerce. The second is the facilitation of product registration processes in multiple nations. The third is to reduce duplicative testing costs. The facilitation of registration is for any new molecular entity—a onetime event for each country; whereas for the facilitation of international commerce and reduction, the duplicative testing remains throughout the lifetime of the product.

Pharmacopeial harmonization is challenging. The fact is that differences exist because of the different histories of the pharmacopeias. There are many factors. The most obvious are: content, language, legalities, speed, and the audiences for the standards. The *USP* applies also to the practice of pharmacy, both in a community pharmacy and hospital, and, thus, the standards set are appropriate to those environments.

There is an obverse to harmony and that is disharmony. An example of disharmony is the need to repeat tests using rabbits for pyrogen where testing for bacterial endotoxin is otherwise prescribed. This represents the most extreme disharmony of methods. But there is a greater disharmony; i.e., reaching different conclusions whether to pass/fail the specimen. In this case, the quality control professionals must make a judgment whether or not this material can be sold in one or more regions. Functionally equivalent to harmonization is the absence of disharmony. Because of a difference in policy, pharmacopeias may differ on adoption of a test. If certain tests are considered necessary by one pharmacopeia in order to protect the consumer, then it is appropriate for

that pharmacopeia to adopt the test without reference to any other region.

Reference Standards

Most discussions of harmonization revolve around excipients or general tests and assays. But the performance of even a harmonized method using different reference standards is not an optimal situation. In fact, harmonization of reference standards preceded many of the harmonization efforts of the last 10 years. Pharmacopeias and the World Health Organization (WHO) have, in the past, shared bulk materials to create their individual reference standards. Where a drug exists as a highly purified crystal, then the difference in pharmacopeial reference standards is administrative and legal in that no difference in results in laboratories is to be seen. This is not the case with mixtures, such as an antibiotic reference standard, which may be established based on different microbiological assays. Hormone records were part of the very earliest reference standard programs.

Biotechnology-derived products have led to renewed interest in establishing reference standards based on the same bulk of material. Thus, a single formulation, assay, and reference standard may be the fact worldwide. This situation can become complex, such as with insulin, where both biotechnology-derived insulin and animal-source insulin are in the marketplace at the same time.

HISTORY OF HARMONIZATION

One of the earliest references to USP's commitment to international harmonization may be found in the historical introduction to the 3rd revision (1) of the *USP* (1851): "The new Dublin and London Pharmacopeias were compared with our own, with a view of introducing uniformity wherever more important considerations did not seem to forbid the requisite modifications." Note that uniformity for its own sake was not the *sine qua non*.

Awareness of the Committee of Revision in 1851 of the importance of keeping the *Pharmacopeia* up-to-date may have been enhanced because of the enactment of the Drug Import Act in 1848, which mandated that drugs imported into the United States had to meet the standards of the country of origin and had to comply with the standards of the *USP* or one of the major European pharmacopeias. The U.S. Customs Service

established laboratories at major port cities and analyzed the imported drugs according to the declared standard. Ties to European medicine remained strong due to Americans traveling to foreign countries for study.

Harmonization of pharmacopeial standards as a practical matter began at the International Congresses of Pharmacy between 1865 and 1910 (2), but the first formal attempt can be traced to 1902. USP President Horatio C. Wood, M.D. and Frederick M. Power, Ph.D., an American chemist of the Wellcome Chemical Research Laboratories of London, were appointed by the U.S. Secretary of State as delegates to represent the U.S. government at the *International Conference for the Unification of the Formulae for Heroic Medicines*, a conference of 19 countries from Europe and North America (3). The second conference occurred in 1918; the third, in 1925, was attended by 31 countries from all continents except Asia and Australia, and was drafted a new "International Convention," which came in force in 1929. It revised the 1902 agreements on 77 "heroic" medicines and introduced the concept of maximum dose. It also requested that the League of Nations create a permanent secretariat of pharmacopeias (4). Andrew G. DuMez, Ph.D., represented the USP, and was officially appointed by the U.S. Public Health Service to represent the United States at this conference (4, 5). An expert committee of the League of Nations planned a third conference for 1938, but it was never convened because of World War II (2).

Other attempts to exchange information among committees for revision of pharmacopeias were attempted through the International Congresses of Pharmacy. Joseph B. Remington, Ph.D., Chairman of the USP Committee of Revision, attending the 1913 conference in The Hague as a delegate of the American Pharmaceutical Association, introduced a resolution to establish an International Bureau of Information to provide information to pharmacopeial revision committees in every country and to operate a testing laboratory. Remington was named to a committee to implement the plan as put forth by Prof. Alexander T. Schirch of Berne, Switzerland (6).

Latin America

Seeking to establish dialogues with Central and South America, the USP, in 1905, responded to a request for a Spanish edition of the *Pharmacopeia* by contracting with Dr. Jose Guillermo Diaz, Dean and Professor of the College of Pharmacy of the University of Havana, Cuba. Support for this project may have come from a

resolution adopted by the Second International Sanitary Convention of the American Republics in 1905, which read in part (3): “Resolved, that a translation of this *United States Pharmacopeia* into the Spanish language would prove of great benefit to the medical profession and pharmacists in each of the republics represented in this Convention.”

The Spanish edition of *USP VIII* was published in 1908. It was adopted by Cuba, Puerto Rico, and the Philippines. Addressing the Convention of 1910, Joaquin Bernardo Calvo, representing Costa Rica, stated (3): “offering to our physicians and pharmacists who do not speak English the *Pharmacopeia* of the United States translated into Spanish; it is one of the most useful works of its kind, if not the most useful, among those published up to the present date.” Spanish editions continued to be published through *USP XV* in 1955. The Spanish edition of *USP XI* was adopted as the official pharmacopeia first by Costa Rica.

In his report to the Convention of 1960, however, Secretary Adley B. Nichols stated (7): “The distribution picture of the *USP* in Spanish has not been satisfactory for some time, and this is especially the case with *USP XV*. In no country is there a marked demand for the translation. Apparently the English language is sufficiently widely known today to permit the use of the readily available English edition.” Perhaps the best summary of why the *USP* produced a Spanish edition of the pharmacopeia can be found in the words of Dr. Charles H. LaWall, Chairman of the Committee of Revision: “The publication of the Spanish edition can never be considered financially advantageous to the Convention, but it should be continued as a patriotic duty and in recognition of the in-use of the book in the Spanish-speaking American countries.”

The *USP* again published in Spanish in 1995, with semiannual supplements since then. This was now possible through “machine translation.” The situation today is mixed, but the English version maintains its importance in Latin America.

MODERN FORUMS FOR HARMONIZATION OF DRUG QUALITY STANDARDS

Forums for harmonization emerged immediately after a *USP* Open Conference in May of 1989 in Williamsburg, Virginia (8). It was concluded there that a thrust should be made toward harmonizing excipients and, possibly, test methods. This position was laid before two international meetings in 1989. The first in Strasbourg,

France, in June of that year, celebrated the 25th anniversary of the *EP* (9). The second, in September, in Tokyo, Japan, sponsored by the Pharmaceutical Manufacturers Associations of Tokyo and Osaka, focused on a theme of drug quality and the role of the pharmacopeias in the year 2000 (10). At both of these well-attended conferences, the representatives of the industry spoke of the need for harmonization of standards among the pharmacopeias representing the major drug discovery and drug manufacturing areas of the world—the United States, Europe, and Japan—to facilitate international commerce in pharmaceuticals.

The areas of pharmacopeial standards most frequently cited at those meetings as in need of harmonization were pharmaceutical excipients and analytical tests and assays. Excipients posed the greatest barrier to commerce as a result of a patchwork of standards in the *USP*, *EP*, and *JP* for a small universe of substances and many natural products of animal, mineral, and vegetable origin that are shared throughout the world. Standards for these common substances reflect cultural, scientific, and temporal differences in how and when these standards were established and last revised. Similarly, differences in tests and assays among the three compendia frequently resulted in situations where meeting the standards of a pharmacopeia in one sector would not predict meeting the standards for that same substance in another sector. That is, testing for the same parameter by another method, often resulting in extra expenditures for capital equipment for laboratories, as well as extra time and resources for conducting the tests and in maintaining trained analysts for different procedures.

PHARMACOPEIAL DISCUSSION GROUP

Founded in Tokyo in September 1989 as the “Quadripartite Group,” the Pharmacopeial Discussion Group (PDG) was originally composed of representatives of the BP, EP, JP, and USP. The current group includes members from the EP, JP, and USP. At its first meeting at the USP headquarters in Rockville, MD, in March 1990, important agreements were reached:

- To meet twice yearly in a small group consisting of the senior staff executive and scientific officers of each pharmacopeia.
- To implement the concept of forward harmonization, which was agreed in Tokyo (10). *Forward harmonization* has three characteristics: a preference for the selection of methods that would be acceptable well into

the future; retaining of any standard meaningful to an individual pharmacopeia; and unilateral progress not inhibited by trying to have every new advance occur simultaneously in every pharmacopeia.

- To include two additional concepts of harmonization: *prospective*—to avoid conflicts among pharmacopeial standards before they occur, and *retrospective*—to resolve conflicts among existing pharmacopeial standards.
- To solicit advice from the pharmaceutical industry and government regulatory agencies on candidate articles for harmonization and their relative priorities.
- To convene open international pharmacopeial conferences.

Articulating the three concepts for harmonization was particularly important. Prospective and retrospective concepts clarify the distinction between work required to avoid conflict when establishing standards for pharmacopeial articles (for which standards do not exist or where few standards exist among the pharmacopeias), from work required to reconcile differences among well-established standards for articles that may have been in the pharmacopeias for considerable time. Prospective harmonization was inaugurated for biotechnology-derived products. Retrospective harmonization focused on pharmaceutical excipients and analytical tests and methods. Forward harmonization expresses a philosophy and environment for harmonization consistent with advances in pharmaceutical analysis.

Establishing a process for harmonization requires recognizing that each pharmacopeia is a sovereign entity, and has certain authorities and obligations derived from the legislation or treaty that created it that harmonization processes must recognize. Complicating the process was the realization that, different from anything that had been attempted before, a forward-moving process was being devised involving the revision systems of three pharmacopeias, each having evolved in different cultures and histories over periods ranging now from 30–180 years, resulting in profound differences in pharmacopeial policies.

Importantly, this was a voluntary effort; there was no legislative or treaty mandate to harmonize. In fact, no organization can compel harmonization. Complicating the process are the differences worldwide trend among the times for appearance of a first monograph, revision publication schedules, public notice and comment opportunities, and updating provisions. The ideal system would allow closely concurrent, if not simultaneous, actions by each pharmacopeia. The realities of level of funding, publication, and acceptance procedures, however, fall short of ideal. As a matter of fact, harmonization takes

resources away from all other pharmacopeial programs because no specified support is received.

The first attempt at soliciting advice for pharmacopeial priorities was the joint issuance of a letter in May 1990 by the USP in English, by the EP in English and French, and by the JP in Japanese (11). It went to the regulatory agencies and pharmaceutical industry associations in the countries and regions served by each of the pharmacopeias. Reflecting the sentiments of the speakers at the 1989 conferences, the letter was devoted to pharmaceutical excipients and asked only three questions: 1) Which excipients have been a source of problem or delay? 2) Has it been necessary to repeat stability or bioavailability studies because of differences in standards for excipients? 3) What are candidates for the top 10 excipients for harmonization? It also asked respondents to identify those specifications, tests, and assays in the monographs for these excipients that are most important to be harmonized.

Responses were returned from individual pharmaceutical companies through their industry associations and the regulatory agencies in the respective sectors. The complete response was compiled by the USP, and a list of the top-10 excipients was developed as the focal point for initial harmonization efforts, after review by each pharmacopeia. The idea of a “*lead*,” subsequently called the *coordinating pharmacopeia*, was adopted, which would take leadership for the revision of the monographs for the excipients for which it had volunteered. The initial list of assignments included: magnesium stearate, microcrystalline cellulose, lactose, starch, cellulose derivatives, sucrose, povidone, stearic acid, calcium phosphate, and polyethylene glycol (12).

The three pharmacopeias have periodicals in which the respective publics are informed of any proposed changes or additional standards (13). Standards do not get out of synchronization through ignorance, because the other two pharmacopeias are familiar with upcoming harmonization-related text in each other's periodicals. And the industry by and large subscribes to all three periodicals and, therefore, should be kept abreast of developments in harmonization. The disconnect arises out of the working speeds and legal procedures of each.

Prospective harmonization is particularly successful when dealing with biotechnology-derived products (14, 15). That is because there are only a couple of manufacturers involved. There should be no reason for the pharmacopeias to arrive at different standards proposed for any particular medicine. This is in stark contrast to the situation where there are multiple manufacturers of drugs no longer covered by patent protection. There is no possibility of harmonization of the some 4000 monographs for individual substances and preparations.

The USP must pay strict attention to the legal situation in the United States. Here, one cannot write "lock-out specifications," thereby keeping somebody out of the business of pharmaceuticals. The other two pharmacopeias, confronted with the same situation, came to the same place in due course, but not at the speed that the USP demonstrates in avoiding any possibility of lock-out specifications. Where there is a valid medical or pharmaceutical reason for specifications that lock out competitors, then the pharmacopeia will set such standards.

One expression frequently heard is to "essentially harmonize." To essentially harmonize is the practical limit of what is possible. It is necessary to rate harmonization on a scale from 0 to 100% harmonized. But in passing judgment, an old expression pertains: "Where you sit is where you stand." The USP's scale for harmonization takes the point of view of a laboratory supervisor who schedules work, training, and capital goods purchases. This would seem to be the point of view that is of most practical value. To assign a quantitative characterization, one must make judgments as to the significance of differences. A completely harmonized requirement would use the same method and establish the same limits. Another, slightly less harmonized requirement would use the same method, but two pharmacopeias would have different limits where one set of limits is nested within the other. If those limits are not nested, then there is a degree of disharmony. Summaries of the overall state of excipient harmony, both from the PDG list and of 200 excipients that appear in *NF* and elsewhere, have appeared in *Pharmacopeial Forum* (16).

The reason a scale for harmonization is necessary is the fact that each pharmacopeial monograph may contain some 10 requirements, and individual monographs will be harmonized on perhaps 7, 8, or even all 10 of those requirements. So where 8 requirements out of 10 are harmonized, it is reported as an 80% harmonized monograph (16).

The goal of harmonization is to bring the policies, standards, monograph specifications, analytical methods, and acceptance criteria of pharmacopeias into agreement. We recognize such unity may not always be achievable. Where unity cannot be achieved, harmonization means agreement based upon objective comparability and a clear statement of any differences. The goal, therefore, is harmony, not unison.

INTERPHARMACOPEIAL OPEN CONFERENCES

Copresented by the BP, EP, JP, and USP, the first Interpharmacopeial Open Conference on Standards for

Excipients was convened in Orlando, Florida, from January 30 to February 1, 1991. Attended by 165 participants, representation included 11 countries, 59 pharmaceutical or excipient manufacturers or suppliers, 3 regulatory agencies (FDA, EEC, and HPB), and 7 pharmacopeias (the copresenters and the French, Italian, and Spanish Pharmacopeias) (17). In preparation for this conference, the USP convened open meetings on magnesium stearate and lactose, attended by almost every major manufacturer from Europe and the USP.

The conference endorsed the goals of the pharmacopeias to improve and harmonize standards for existing excipients, to focus on testing methods and address specifications after test methods had been agreed upon, and to develop functionality tests, including particle size, surface area, and density.

Implementation of the open conference recommendations led to a change in configuration of the membership in the pharmacopeial harmonization process. Whereas the BP had been an independent member of the Quadripartite Group from its inception, implementation of harmonization of standards and tests for excipients was recognized as a regional matter under the aegis of the EP, and the BP's independent membership in the process ended. The resulting group of the USP, JP, and EP became known as the PDG and has continued its efforts in tripartite configuration.

A second Joint Pharmacopeial Open Conference on International Harmonization of Excipients was held in St. Petersburg, Florida, in January, 1994 (18). Major progress was achieved and established the principle that conferences were the key component of harmonization. Progress on pharmacopeial harmonization was reported at the International Conference on Harmonization in Brussels in November 1991, and activity of the PDG to fulfill its goals is high. Several tangible and important milestones have been reached. First and most important is the recognition by the JP of its need to develop a vehicle for public notice and comment for pharmacopeial revision, and the essentiality of such a vehicle to the communication process. Recognizing that need, the JP reached a decision to publish the *Japanese Pharmacopoeial Forum* (JPF) on a quarterly basis. The first edition in January 1992 (11) included proposals for the revision of magnesium stearate and lactose monographs. Notable also is the fact that matters in JPF relating to international harmonization are printed in English, whereas domestic revision matters appear in Japanese.

A second milestone was a letter by the PDG in May 1992 soliciting further candidates, beyond excipients. Responses to that inquiry focused primarily on tests and assays. Replies were ranked by order of priority. The priority of

excipients was expanded to the top 25, based on further analysis of responses. The lists of combined assignments and priorities for pharmacopeial harmonization appeared in the forum publications of the pharmacopeias (12, 13).

JP took another step toward harmonization by announcing that it would implement an annual supplement program to update the *JP* between editions, beginning with an October 1993 supplement to *JP XII* (11).

Refinement of the process of pharmacopeial harmonization occurs ongoing (see Fig. 1 and Appendix which details the process as of December 1999). Accommodating the revision processes, time requirements, and publication schedules of three revision systems and nine publications proved infeasible as initially envisioned. It required continual adjustment as issues reach stages in revision that had not been foreseen or did not fit within existing systems. Also complicating progress was that, although the USP in 1980 established the first expert group that focused on excipients (Subcommittee on Pharmaceutical Ingredients), the other pharmacopeias did not have task groups readily at hand devoted specifically to excipients.

Experience gained by harmonizing the first of the excipients (lactose and magnesium stearate) showed that, because so many parties are affected and multiple expert groups must be convened, forward, retrospective harmonization is intrinsically a multiyear process.

TESTS AND STANDARDS

Impurities in Excipients

Limit tests have a long standing in pharmacopeias. For some (heavy metals is an example), the sensitivity of the method was the basis for the standard. Modern limits in the *USP–NF* are toxicity based. There is divergence in harmonization because of toxicity-based rather than method-based standards. The modern basis avoids the exclusion of safe products from the marketplace, whereas the older approach could lead to lock-out specifications considered technical barriers to trade.

Biotechnology-Related Standards

Implementation of prospective harmonization began formally with a second conference on standards for biotechnology-derived products. The conference was attended by about 150 scientists and regulators from 20 countries. With participation by experts on pharmacopeial revision bodies from each of the three pharmacopeias, the conference produced a series of recommendations relating to informational chapters, general chapters on tests and

assays, and group and individual monographs for selected biotechnology-derived human drugs and biologics (14).

The introduction of biotechnology-derived products presented a decisive moment (15): an opportunity to avoid conflicting standards through the commitment of the pharmacopeias to the process of harmonization for pharmacopeial standards for an emerging technology. Included in this opportunity are the practical values obtained from common reference standard materials.

The complexity of the technology, in concert with medical conditions, and clinical environments, and the desire for instant globalization of return on investment call for facilitation and avoidance of ambiguities by uniform standards worldwide.

Biotechnology-derived drugs are of mutual interest to the USP and the International Conference on Harmonization on Drug Quality (ICH-Q6). The relationship is uncertain between compendial standards and the development and approval of biotechnology-derived drugs by regulatory agencies. The *USP* contains many general chapters (i.e., “horizontal standards” such as stability, injections, and bacterial endotoxins), which are cited extensively by the biotechnology industry, and an informational chapter on biotechnology-derived products that explains terminology and facilitates communication.

Status of Interpharmacopeial Harmonization

Supplements to *USP24–NF19* contain updates of an informational chapter by this name. It lists all of the projects undertaken by the PDG. Appendixes list the projects as of January 2000, and identify the coordinating pharmacopeia. However, these do not report the official status of each project because this changes with each supplement.

Because revision programs work on different schedules, one should compare only the current texts of two or more pharmacopeias whenever divergence of mandatory requirements is an issue. The official pharmacopeial texts should be compared.

Harmonization proposals do not have official status. The work of the PDG is finished at Stage 5B. The progress of the harmonization projects can and should be verified in the most recent number of the periodicals: *Pharmacopeial Forum*, *Japanese Pharmacopoeial Forum*, and *Pharmeuropa*. For standards in force in *USP24–NF19*, see also the latest supplement or Interim Revision Announcement.

Equivalence

Tests and assays of the EP and the JP that have been elaborated through the PDG Procedure are considered as

equivalent to *USP–NF*, except as noted in Chapter <1196> entitled *Status of Interpharmacopeial Harmonization* found in supplements to *USP24–NF19*. Because the legal status of each may not be at the same stage, a precautionary check should be made to support any plans or actions.

Equivalence is attributed to those monographs, tests, or assays that have arrived at Stage 5B. The nature and reason for divergences are expected to be described in the three pharmacopeial periodicals. Only those stated exceptions are considered nonequivalent.

INTERNATIONAL CONFERENCE ON HARMONIZATION

Founded in 1990, the International Conference on Harmonization (ICH) is comprised of the pharmacopeial manufacturers associations in Europe (EFPIA), Japan (JPMA), the United States (PMA), and the drug regulatory agencies in Europe (EEC), Japan (MHW), and the United States (FDA), with the International Federation of Pharmaceutical Manufacturers Association (IFPMA) serving as secretariat. Pharmacopeias are not members of the ICH, where membership is reserved for three PMAs and three regulatory agencies. Invited observers include Canada, WHO, and the European Free Trade Association (EFTA).

With expert working groups in the areas of drug efficacy, drug safety, and drug quality, the ICH is the foremost opportunity for harmonization among the leading drug regulatory and manufacturing groups in the world. The ICH Expert Working Group on Drug Quality (EWG-Q) includes the topic Q4, “Pharmacopeias.”

The pharmacopeias have worked with the ICH process to facilitate the international environment of pharmaceutical research and product registration. On the other hand, the additional situation for compendia is that the standards that they have published now apply to all of the products already marketed. In that case, a company has testing history in their quality control (QC) departments. The QC departments are the most conservative elements within the pharmaceutical industry—an attribute necessary to their task. QC departments are reluctant to change methods when they feel that their products are properly represented by their current suite of tests. Thus, there is resultant tension between trying to develop harmonized standards that facilitates one area of activity in the world of pharmaceuticals and not disturbing a satisfactory marketplace. A vast amount of progress has been made in harmonization of pharmacopeial methods.

At the first biennial meeting of the ICH in Brussels in November 1991, the United States, Japanese, and

European Pharmacopeias presented papers relating to progress being made in the harmonization of pharmacopeial standards for excipients (19). Other topics, such as stability, validation, impurities, and biotechnology, were established. The pharmacopeias are involved in all these issues. In fact, *USP* general chapters served as background for harmonization for some of these topics.

The ICH Steering Committee responded favorably to a request by *USP* for *observer status*, recognizing it as a nongovernment, nonindustry body with official status under U.S. statutes. Now, each of the three pharmacopeias can participate in EWG-Q activities and in ICH biennial meetings as independent bodies.

Stability is a key quality concern that is addressed in various ways by pharmacopeial standards. It was also the first subject for which the EWG-Q developed a guideline. The *USP* has redefined the concept of *Controlled Room Temperature* in terms of a Mean Kinetic Temperature of 25°C, which is identical with the long-term storage temperature promoted by ICH. Furthermore, ICH has advised against including recommended storage label statements that could conflict with United States, or other regions’ practices. Thus, the *USP* standards and the ICH guideline agree on this overarching concern for the stability of pharmaceuticals. The *USP* actively participated in achieving this desirable outcome.

Validation of analytical procedures is intrinsic to both new drug approval and compendial revision. The *USP* had already established an informational chapter, <1225> entitled *Validation of Compendial Methods* before the international harmonization effort began—a joint effort among the Pharmaceutical Research Manufacturers Association, the FDA, and the *USP*. It was useful in the work of the EWG-Q to prepare a document on validation of analytical procedures that concentrated on the submission of a new drug to the reviewing authorities. Later, in response to demands of users, the ICH document was expanded to more readily meet the scope of *USP* <1225>. Differences that arose were resolved, thereby securing the harmonized situation. The emergent ICH document and the *USP* chapter are harmonized in breadth and detail in such a way that the vocabularies of validation and the underlying analytical strategies are in concert.

A recommendation by the PDG to establish a harmonized procedure for stability to light was taken up by the EWG with Japanese participants responsible for a first draft of a guideline. A harmonized procedure emerged, again for the purpose of new drug approval.

Impurities are of many kinds, and, therefore, the issues for harmonization are numerous. Everyone concerned agrees that toxic impurities must be controlled at very low

levels, and the analytical difficulties in measuring low levels limit choice. It follows that harmonization of methods is straightforward, once the objectives of analysis are laid out. Both, the USP and ICH limit measurement to impurities at or above 0.1%, which is of practical significance in everyday commerce in bulk pharmaceutical chemicals. In addition, the ICH guideline refers to the pharmacopeial limits on toxic impurities, such as heavy metals. Thus, on all critical issues, there is no conflict between the ICH guideline for new chemical entities and established USP impurity policies, which apply to hundreds of drugs already on the market. The USP further identifies as signal impurities those that are distinctly informative of the purification or decomposition of a drug substance. The remaining impurities are considered in nonspecific categories of ordinary impurities and a labeling requirement for other impurities and are limited to 2% total. ICH sets no such ceiling limit. These policies do not require disclosure of proprietary synthesis or purification details, yet they accomplish the necessary task of limiting bias, thereby assuring meaningfulness of tests and assays. But here ICH guidelines demand identification of each impurity and of individual limits, requiring detailed lot-to-lot bookkeeping on all impurities. Impurities in excess of 0.1% are to be “qualified” (i.e., toxicity considered); USP policy requires notification to USP of any known toxic impurities.

For some years, the USP had a requirement on organic volatile impurities. When the EP was adopting a similar requirement, it was clear that toxicologists on different sides of the ocean would come to different conclusions as to appropriate limits on solvents. At the request of the pharmacopeias, this topic was taken up by (EWG-Q). The effort was successful, and a guideline on residual solvents emerged. Relative to the existing USP limits, it was necessary to revise some upward and others downward, but none to any great extent. This new effort was 15 years subsequent to the initial exercise. However, there remains an unresolved solvent and that is benzene.

Specifications Documents

The ICH–EWG–Q produced two guidelines, Q6A and Q6B, dealing with specifications to support a new drug registration. Biotechnology-related specifications are treated by Q6B, and all others that were previously the subject of EWG-Q guidelines are treated by Q6A. Pharmacopeial methods are intrinsic to these guidelines.

ICH–EWG–Q developed a list of 12 general chapters (tests and assays) that were deemed critical to new product registration and urged the PDG to concentrate on prompt

harmonization (see Appendix III). One of these, *Antimicrobial Preservatives Effectiveness*, was dropped in 1999 when nonharmonizability was clear because of differences in the essence of utilization of the same microbiological procedure. Of the 11 remaining chapters, all but two (*Microbial Limits of Non-sterile Articles* and *Dose Uniformity*) were harmonized with regard to scientific content by the end of 1999; only the necessary publication sequences were unfinished.

The Q6A and Q6B documents were preceded by the North American Conference on Specifications. In all cases, no method selection, scope of application, or overall policy (dissolution, impurities, particulate matter, etc.) is at odds with USP—a remarkable situation in view of the breadth of the topics covered. The main difference was and is the proportion of active ingredient in a formulation that triggers choice of determination of content or of weight to establish uniformity of dosage units.

Concordance

In the future, harmonization could be accelerated by reference to laboratory data, rather than by trying to achieve harmonized texts, tests, or assays that establish the same attribute of an article (i.e., water by titration vs. loss on drying). Inherent in this allowance is the assumption that concordant methods can be shown to yield comparable outcomes with regard to acceptable identification, strength, quality, purity, bioavailability, or labeling in the context of the monograph of a recognized article. In the event of a dispute, however, only the result obtained by the procedure given in the appropriate pharmacopeia is conclusive.

This concordance rests on the probable presumption of good manufacturing practices in production and control, now a reasonable presumption in today’s international environment.

The use of concordant methods does not necessarily require identical reagents, procedures, or measurements. Official procedures of pharmacopeias, per se, require no validation, but validation of the applicability of official procedures to each preparation (formulation) is to be presumed (e.g., the presence of interfering ingredients).

Concordance would facilitate international commerce in official articles by allowing the reduction of duplicative testing or delay in national product registration or approval proceedings. No provision of the USP General Notices is abrogated, and the allowance, therein, for alternative methods is not foreclosed by a monograph citation to the concordance.

As stated in the General Notices, an article is recognized in *USP–NF* when a monograph for the article

is published in it. Each monograph contains standards that define an acceptable article, and gives tests and assays and other specifications designed to demonstrate that the article is acceptable. Monographs and their interpretation are subject to the provisions of the General Notices and general chapters. The tests and assays required in a single monograph are intertwined, therefore, and may further state any necessary variation from the designated general chapters or the General Notices. That is, pharmacopeial monographs define interdependent attributes, each drawn in light of other monograph requirements and the General Notices and must be viewed in total. Consequently, allowances for concordance would only be utilized when supported by an initial verification through duplicate testing of the same specimens and evidence that both methods were validated.

APPENDIX I: WORKING PROCEDURES OF THE PDG

Stage 1: Identification

PDG identifies subjects to be harmonized and nominates a coordinating pharmacopeia for each subject.

Stage 2: Investigation

The coordinating pharmacopeia for a subject to be harmonized collects the information on the existing specifications in the three pharmacopeias, on the grades of products marketed, and on the potential analytical methods. For new products or new methodologies, existing information in the scientific literature or from manufacturers is collected and analyzed. The coordinating pharmacopeia prepares a draft monograph or chapter, accompanied by a report giving the rationale for the proposal, with validation data where appropriate and available. Stage 2 ends with the proposal draft, which is mentioned in this procedure as the Stage 3 draft. The Stage 3 draft, accompanied by supporting comments or data that explain the reasons for each test method or limit proposed, is sent by the coordinating pharmacopeia to the secretariats of the other two pharmacopeias.

Stage 3: Proposal

The three pharmacopeias publish the Stage 3 draft in the next available issue of their forums, in the style provided by the coordinating pharmacopeia. If necessary, questions are addressed to the readers of the forums when specific

issues require their advice, information, or data. In *Pharmeuropa* and the *Japanese Pharmacopoeial Forum*, the Stage 3 draft is published in a specific section entitled *International Harmonization*. In the *Pharmacopeial Forum (USP)*, the Stage 3 draft is published in the *Pharmacopeial Previews* section. The draft is published in its entirety. The corresponding secretariats may have to add information needed for the understanding of implementation of the texts, e.g., the addition of the description of an analytical method or of reagents that did not exist in the pharmacopoeia. Comments by readers of these forum resulting from this preliminary survey are to be sent to their respective pharmacopeial secretariat, preferably within 4 months of publication. The period for public review and comment should not exceed 6 months, however. Each pharmacopeia analyzes the comments received and submits its consolidated comments to the coordinating pharmacopeia within 2 months of the end of the public review/comment period. The coordinating pharmacopeia reviews the comments received and prepares a harmonized document (Stage 4 draft) accompanied by a commentary discussing comments received regarding the previous text and providing reasons for action taken in response to those comments. The Stage 4 draft together with the commentary is sent to the secretariats of the other pharmacopeias (end of Stage 3).

Stage 4: Official Inquiry

The Stage 4 draft is published in the *forum* of each pharmacopeia, with the style adapted to that of the pharmacopeia concerned. In *Pharmeuropa* and the *Japanese Pharmacopoeial Forum*, the Stage 4 draft together with the commentary is published in a specific section entitled *International Harmonization*. In *Pharmacopeial Forum*, the Stage 4 draft is published in the *In-Process Revision* section. Comments regarding this draft are to be sent by readers of the forum to their respective pharmacopeial secretariat, preferably within 4 months and at most within 6 months of publication in the forum. Each pharmacopeia analyzes the information received and submits its consolidated comments to the coordinating pharmacopeia within 2 months of the end of the review/comment period. The coordinating pharmacopeia reviews the comments received and prepares a draft harmonized document (Stage 5A draft), accompanied by a commentary discussing comments received regarding the previous text and providing reasons for action taken in response to those comments. The Stage 5A draft, together with the commentary, is sent to the secretariats of the other two PDG members (end of Stage 4).

Stage 5: Consensus

- a. *Provisional.* The stage 5A draft is reviewed and commented on by the other two pharmacopeias within 4 months of receipt. The three pharmacopeias shall do their utmost to reach full agreement at this stage, with a view to reaching a final consensus. If the consensus is reached, a Stage 5B draft is developed. In those rare instances where consensus is not reached or where novel, unanticipated serious issues are identified by any of the parties and need to be considered, depending on the complexity and gravity of the issues, more than one mechanism for resolution may be adopted. This includes the coordinating pharmacopeia call for a meeting of experts from the three pharmacopoeias to search for a consensus. This group prepares a modified 5A document (5A-2) that will be published in the three forums for public comments. These are then reviewed by the group of experts that finalized the consensus document (5B).
- b. *Final.* When consensus has been reached, the Stage 5B draft (consensus document) is sent by the coordinating pharmacopeia to the other pharmacopeias for final sign-off.

Note: The last two stages of the implementation of the “harmonized” chapters and monographs take place individually, according to the procedures established by each pharmacopeial organization.

Stage 6: Adoption

The document is submitted for adoption to the organization responsible for each pharmacopeia. Each pharmacopeia incorporates the harmonized draft according to its procedure. If necessary, the Stage 5B draft can be adopted, with specific amendments identified as such, corresponding to a general policy in the territory of the pharmacopeia in question. The monographs may, therefore, be harmonized, without being identical in every respect. Adopted texts are published by the pharmacopeias in the Supplements or, where applicable, in a new edition/revision. If a consensus has not been reached at Stage 5A, the pharmacopeias prepare together an article on divergences to be published by all three pharmacopeias in the respective forums.

Stage 7: Date of Implementation

The pharmacopeias will inform each other of the date of implementation in the particular region.

APPENDIX II: EXCIPIENT HARMONIZATION

Excipient	Coordinating pharmacopeia
Alcohol	EP
Benzyl alcohols	EP
Dehydrated alcohol	EP
Calcium disodium edetate	JP
Calcium phosphate, dibasic	JP
Calcium phosphate, dibasic (anhydrous)	JP
Carboxymethylcellulose, calcium	USP
Carboxymethylcellulose, sodium	USP
Carboxymethylcellulose, sodium (cross-linked)	USP
Cellulose (microcrystalline)	USP
Cellulose (powdered)	USP
Cellulose acetate	USP
Cellulose acetate phthalate	USP
Citric acid (anhydrous)	EP
Citric acid (monohydrate)	EP
Crospovidone	EP
Ethylcellulose	EP
Hydroxyethylcellulose	EP
Hydroxypropylcellulose	USP
Hydroxypropylcellulose (low-substituted)	USP
Hydroxypropylmethylcellulose	JP
Hydroxypropylmethylcellulose phthalate	USP
Lactose (anhydrous)	USP
Lactose (monohydrate)	USP
Magnesium stearate	USP
Methylcellulose	JP
Methyl parahydroxybenzoate	EP
Petrolatum	USP
White Petrolatum	USP
Polyethylene glycol	USP
Polysorbate 80	EP
Povidone	JP
Saccharin, calcium ^a	USP
Saccharin (free)	USP
Saccharin, sodium	USP
Silicon dioxide	JP
Silicon dioxide (colloidal)	JP
Sodium chloride	EP
Sodium starch glycolate	USP
Starch, corn (maize)	USP
Starch, potato	EP
Starch, rice	EP
Starch, wheat	EP
Stearic acid	EP
Sucrose	EP
Talc	EP
Titanium dioxide	JP
Ethyl parahydroxybenzoate	EP
Propyl parahydroxybenzoate	EP
Butyl parahydroxybenzoate	EP
Glycerol	USP

^a The JP declines to participate in harmonization, so the USP and EP will harmonize bilaterally.

Note: PDG affirmed that harmonization was not to be undertaken in view of the different drinking waters standards elaborated by various governments. See the monograph for Purified Water.

APPENDIX III: STATUS OF GENERAL TESTS AND ASSAYS

	Coordinating pharmacopeia	ICH-Q6 lists
Dissolution ^a	EP/USP	*
Disintegration	EP/USP	*
Dose uniformity ^b	JP/USP	*
Color and clarity	EP	*
Extractable volume	EP	*
Heavy metals	USP	*
Particulate matter	EP	*
Residue on ignition—sulfated ash	JP	*
Sterility	EP	*
Bacterial endotoxin	JP	*
Microbial contamination	EP	*
Preservative effectiveness ^c	EP	*
Particle size distribution estimation by analytical sieving	USP	*
Inhalations	EP	
Bulk density and tapped density	EP	
Optical microscopy—powder fineness	USP	
Powder flowability	USP	
Specific surface area	EP	
Tablet friability	USP	

^aApparatuses 1, 2, and 4 are harmonized. Not all apparatuses appear in other pharmacopeias, and decision rules are harmonized. Approach to selection of media is not harmonized and may not be a valid subject in view of population and formulation differences.

^bIncludes content uniformity and weight variation.

^cIn view of two-test nature of an otherwise highly similar procedure used in different modes in US and Europe, this is nonharmonizable on test times and decision values.

Handling Hazardous Chemicals and Pharmaceuticals

Antonio Conto

ChemSafe Sas, Colletterto Giacosa (TO), Italy

INTRODUCTION

Over the last few years, legislation on the safety of chemical substances for humans and for the environment has been completed. Chemicals manufactured, imported and, in any way, handled by pharmaceutical and chemical companies are covered by a number of laws, which have been reinforced at all national levels.^[1,2] The United States and European requirements differ in some ways as to the application of safety parameters, but a good reciprocal acceptance on safety data exists. The safety of chemicals is evaluated through a number of physico-chemical, toxicological, and ecotoxicological studies standardized by the international evaluation agencies. Risk assessment (RA) of these chemicals is performed based on such experimental data, the use of the chemical, and possible exposure to humans and the environment.^[3] In Europe, there is a long-standing harmonized system (since 1981) that evaluates the final classification and labeling of a chemical and the so-called new or existing chemicals. In the United States, chemical safety is regulated by the Toxic Substance Control Act (TSCA) and the Code of Federal Regulation (CFR),^[4] and is managed by the Environmental Protection Agency (EPA). The Food and Drugs Administration (FDA) focuses on the registration of novel drugs in the American market. One basic step of the approach for handling a hazardous chemical is its classification and subsequent labeling. The classification is reported in the Safety Data Sheet (SDS), which is a tool that informs workers and operators about the possible hazards and risks related to the substance. The handling of hazardous chemicals must also observe the occupational exposure limits as well as medical advice rules, which provide first aid in case of accidental spillage or exposure to the chemical. To handle a hazardous chemical correctly, we need to know a lot about it [e.g., legislation that covers its handling, methods for testing the hazards and consequent risks for humans, possible efficacy (in case of active principle ingredient, or API), epidemiological data, and classification and labeling]. Pharmaceuticals are substances intended for human therapy, but because they are internally handled during the manufacturing phases (production, formulation, packaging, etc.), concerns for the safety of workers and the environment arise.

In this article, we will go through the safety concepts that can be applied to a chemical substance to give the readers a general overview of the matter. The safety of hazardous pharmaceuticals is a field that can be included in this approach, and many suggestions or proposals regarding pure chemicals will be discussed. The term “chemicals” is used interchangeably with pharmaceuticals because all pharmaceuticals are, in essence, chemicals.

DEFINITIONS

Table 1 shows some definitions that can help the readers.

LEGISLATION AND REQUIREMENTS

We will refer to two main approaches to the safety of new chemicals: that applied in the United States and that applied in Europe.

United States

The so-called premanufacturing notification (PMN) is regulated by the EPA through the TSCA, which has been in force since January 1, 1977.^[1] The notification process and the assessment system for new chemicals became operative in July 1979. All substances imported into the United States (including pharma intermediates, which are considered chemicals from a regulatory point of view) have to be listed in the TSCA Inventory of Chemical Substances, unless they are imported in low quantities for research and development (R&D) purposes. Requests for limited notifications may be accepted for the following types of products: new chemicals imported or produced in quantities of 1000 kg/year or less, new chemicals used for the production or processing of instant photographic or peel-apart film articles, and some polymers.

The PMN approach also applies for known substances destined for a significant new use (Significant New Use Rule). If the substance is on the list and it is still destined for the use shown (no SNUR), the production/importation can take place. If the substance is not listed, the PMN

Table 1

Chemical substances	Chemical elements and their compounds in the natural state, or obtained by any production process, including any additive necessary to preserve the stability of the products and any impurity deriving from the process used
Hazardous pharmaceuticals	Substances that can be considered of concern based on intrinsic toxic characteristic, or in relation to their exposure to humans and the environment
Preparations	Mixtures or solutions composed of two or more substances
Placing on the market	The making available of the substance to third parties
NONS	Notification of new substances
EINECS	European Inventory of Existing Chemical Substances
ELINCS	European List of Notified Chemical Substances
PMN	Premanufacturing notification (USA)
USA OSHA	Occupational Safety and Health Agency
USA NIOSH	National Institute for Occupational Safety and Health
ICCA	International Council of Chemical Association
HPV	High production volume
QSAR	Quantitative structure–activity relationship
LD ₅₀	Lethal dose that kills 50% of the experimental animals
NOAEL	No Observed Adverse Effect Level
NOEL	No Observed Effect Level
OEL	Occupational Exposure Level
SDS	Safety Data Sheet
PPE	Personal protection equipment
API	Active principle ingredient
RA	Risk assessment

process is followed. The PMN must be presented at least 90 days before the production of the new substance. New substances presented with a PNM are added to the list only after a 90-day review period and after the producer has submitted the so-called Notice of Commencement (NOC) within 30 days of the start of production. The notifier is asked for the following information: Chemical Abstracts Service (CAS) number, chemical name, structural and molecular formulas, trade name, spectral analysis, type and percentage of impurities, and use. Initially, no experimental data are requested; but if valid data are available, they must be included. Existing chemicals (those already listed) can be classified and consequently handled based on criteria given by the Occupational Safety and Health Agency (OSHA) and the National Institute for Occupational Safety and Health (NIOSH).

Europe

The European procedure involves the conduction of a testing program (toxicology, ecotoxicology and physico-chemical properties) based on the tonnage of the substance (annual or total production) to be notified in the European Union (EU) market. A final dossier containing all the data on safety, production, storage, handling, and disposal must be prepared.^[2]

The dossier must also include a proposal for the classification and labeling of the test substance, along with an RA for humans and the environment. The levels of notification requested in Annexes VIIC, VIIB, and VIIA of EEC Directive 92/32 are to be considered standard programs (minor changes may be introduced depending on the physicochemical features of the substance); for subsequent levels (Annex VIII), all the European Authorities must discuss and agree on the testing program to be carried out. The ecotoxicological profile of the substance from the previous level is obviously taken into account.

The EU Directive 67/548 and its latest amendment (EEC 92/32) consider “new” those chemicals not listed in European Inventory of Existing Chemical Substances (EINECS) and not belonging to the following categories for which specific community laws are in place: pharmaceuticals such as API, pesticides, cosmetics, biocides, and food additives. Exemptions may be obtained for products under R&D or for process-oriented R&D (PORD) products.

Particular attention is paid to the use of animals in testing; a product already notified cannot undergo a new testing program, but the two applicants are obliged to share toxicology data.

Existing chemicals are covered by specific regulations that set up a priority list system.^[5] Preparations are

classified and labeled by adopting a theoretical approach based on the hazard of each single component as detailed in the European Directive 45/1999.^[6]

TESTING ON CHEMICALS

The actual evaluation of the possible hazards of chemicals and the risk to humans handling such chemicals is based on data obtained from animal studies.^[7,8] This approach is constantly under discussion in terms of the ethical use of animals and some difficulties in adapting animal data to humans.^[9] Thanks to years of research, a huge amount of data on chemicals already exists, and the availability of data banks means that it is easy to access. Nevertheless, many chemicals are still unclassified for safety, and much research still needs to be done. Over the last 3 or 4 years, some industry associations have launched programs focused on testing chemicals to cover the lack of safety information, namely ICCA and HPV initiatives.^[10] Furthermore, some theoretical new tools such as the family approach and the quantitative structure–activity relationship (QSAR) are now available. These approaches are now under validation processes, which hopefully will lead to their use for regulatory purposes.

The current testing package, which checks the hazards of a chemical, consists of the following studies:

- Oral, dermal, and inhalation acute toxicity testing.
- Dermal and ocular irritation studies.
- Skin sensitization studies.
- Mutagenicity studies (basically Ames and chromosomal aberration).
- Repeated dose toxicity (subacute and chronic) studies.
- Reproductive and carcinogenicity studies.
- Ecotoxicology studies for the environmental impact.
- Studies to identify endocrine-disrupting chemicals.
- Physicochemical profile.

The research program has a tiered approach starting from the acute profile up to the most important studies such as chronic toxicology, carcinogenicity, and reproductive studies.

At the end of the process, we will be able to classify the chemical substance and to understand which handling safety procedures are the most suitable.

The aim of the experimental studies is to determine a number of toxicological parameters that will serve as a basis in classifying a substance.^[7] The most important are:

- LD₅₀, the lethal dose that kills 50% of the treated animals; this is determined by acute studies.
- The potential to be irritating to skin and eyes, and the sensitization effects.

- The No Observed Adverse Effect Level (NOAEL) and the No Observed Effect Level (NOEL) determined by repeated dose studies.
- Some intrinsic physicochemical properties that can lead to risks for humans or the environment.

Normally, those chemicals classified as highly toxic, highly sensitizing, carcinogenic, or affecting the reproductive/fertility field are considered very dangerous and very risky for humans, and special containment and safety procedures are required for them. In some cases, they are banned from the market or from use in chemical industries.

CLASSIFICATION AND LABELING

The classification of a chemical substance is focused on three main areas: physicochemical properties, toxicology, and ecotoxicology.

Based on current regulations, a substance may be classified as detailed in Table 2, which reports the possible classification class and the related letter for the label on the packaging.^[11]

The next step is to label the substance based on the classification obtained. The label must include all necessary information to inform the users about the hazards of the substance, as indicated in Table 3.

SAFETY DATA SHEET

The SDS is a document for users, which contains all the information on the substance. In particular, it provides information that is useful for the handling of chemicals.^[12] It is normally composed of a number of paragraphs focused on specific information.

Table 4 shows the structure of a typical SDS.

Table 2

Possible classification	Letter
Explosive	E
Oxidizing	O
Highly flammable	F
Extremely flammable	F ⁺
Toxic	T
Very toxic	T ⁺
Corrosive	C
Harmful	Xn
Irritant	Xi
Dangerous to the environment	N

Table 3

Information to be reported	Explanation
Name of the chemical	Chemical name of the substance
Name of the manufacturer	Full address including emergency numbers
Symbol	A picture requested by laws clearly showing the type of danger (a flame, a skull, etc.)
Letter	The abovementioned letter of danger identification (E, O, F, T, etc.)
R phrases	Risk phrases describing the danger (e.g., R25, toxic if swallowed)
S phrases	Safety phrases in case of accidental exposure (e.g., S24, avoid contact with skin)
Other indications	If needed

HANDLING

The handling of hazardous chemicals or pharmaceuticals is a consequence of all the abovementioned activities. It is obviously affected by different parameters that enter into the final evaluation. The first is the intrinsic hazard of the chemical. This is evaluated, as discussed, through a number of appropriate tests. However, the knowledge of such elements is not sufficient to calculate the risk of the chemical for humans. A simple rule says that the final risk is related to the exposure of the chemical to humans. This leads us to believe that handling is something that can considerably decrease the rate of exposure and, consequently, the risk. Low toxic substances with high ex-

posure can be more dangerous than highly toxic substances with a low (or no) exposure.^[7] This means that handling/manipulation procedures are the key factor to reducing possible effects on workers or, if not applied correctly, to amplifying adverse effects on humans that can lead to very severe health problems, especially after long exposures.

When approaching the problem, the first parameter that needs to be carefully evaluated is the possible route of exposure.^[13] Inhalation route related to the presence of thin powders is the most dangerous way of affecting the human body. This can cause respiratory problems in the lungs, or sensitizing problems, or, in worst cases, cancer of the lungs. The second route of exposure is, without

Table 4

Paragraph number	Title	Information included
1	Identification of the substance and company	Chemical name, company name, reference person, and emergency numbers
2	Composition/information on ingredients	Chemical names
3	Hazard identification	Description of possible hazards based on testing
4	First aid measures (FAMs)	Detailed explanation of FAM related to different exposure routes
5	Fire-fighting measures	Based on the recorded physicochemical properties
6	Accidental release measures	Including personal and environment precautions; cleaning procedures
7	Handling and storage	How to handle and store with PPE description
8	Exposure control/personal protection	Including, if available, TWA, TLV, OEL limits
9	Physical and chemical properties	Based on testing
10	Stability and reactivity	If available
11	Toxicological information	Based on testing
12	Ecological information	Based on testing
13	Disposal consideration	Possibility of recycling/neutralizing waste residuals, etc.
14	Transport information	Classify for transport (UN numbers, etc.)
15	Regulatory information	Classification and labeling are reported here
16	Other information	If necessary
	Disclaimer	If deemed necessary by the company

Table 5

Exposure route	PPE	First aid measures
Inhalation	Dust mask, self-contained breathing apparatus in the worst cases	Remove the persons from the exposed area to fresh air immediately
Dermal	Protective clothing, gloves	Remove contaminated clothes and shoes immediately; wash the area with soap or mild detergent and rinse thoroughly until no evidence of substance remains (15–20 min)
Eyes	Protective glasses	Wash immediately with plenty of water or normal saline; keep eyelid open
Ingestion	Face mask	Wash mouth with water if the person is conscious; treat symptomatically and supportively

doubt, the dermal route, through which local effects (irritation, dermatitis, and redness) or systemic effects (toxicity or sensitization) can be determined. The third route is the oral route, which is less common but causes high toxicity in case of accidental ingestion of the chemical. This route is used less among skilled company workers but maybe used in the public at large due to accidental reasons.

Compounds classified as harmful or toxic in these routes of exposure must be handled with specific procedures and personal protection equipment (PPE) in almost all phases of their manipulation during chemical processes. Compounds classified as highly toxic, highly sensitizing, carcinogenic, or affecting the reproductive system should be used in sealed areas or closed systems with no possible exposure to humans by any route.

Table 5 shows the containment/handling and first aid procedures in relation with the different possible routes of exposure of humans (assuming the substance shows adverse effects).

Medical advice from the company medical doctor is required if any symptom appears within a few minutes after exposure, or in cases of considerable acute exposure.

The medical doctor is responsible for adopting all the suitable therapies based on the symptoms observed and in relation to the information written on the label of the chemical.

Based on physicochemical testing, a different approach to the manipulation of the chemical is needed; this is more related to storage conditions than to the handling itself. Particular care must be taken with explosives, flammables, and oxidizing substances in terms of labeling, packaging, storing, and handling. Table 6 shows the containment/handling procedures based on the intrinsic characteristics of the substance.

Special handling provisions are foreseen for those chemicals classified as dangerous to the environment. Do not allow the substance to enter the drainage system, surface water, ground water, and soil. Therefore, storage must be severely controlled. The release of the substance in the environment is severely banned and reference to local/national rules/laws must be followed.

All residuals from empty containers and cleaning of reactors must be stored, well labeled, and disposed of by specialized waste disposal companies. Incineration is normally suggested as the best method of disposal. The amount of waste must be controlled and kept to a minimum.

All substances classified as highly toxic, highly sensitizing, carcinogenic, or affecting the reproductive system must be used in a sealed area or in a closed system in the chemical plant to avoid any possible exposure to humans. If the chemical plant has some weak points where a possible leakage or exposure could occur, all the PPE must be available.

Table 6

Characteristics	PPE	First aid measures
Explosive	Protective clothing	Avoid shock, friction, and heating; store the sample clearly labeled in a well-ventilated room
Flammable	Protective clothing	Avoid any contact with flame sources; store the sample tightly closed and clearly labeled in a controlled area; avoid smoking
Oxidizing	Protective clothing	Avoid contact with flammable materials; store the sample tightly closed and clearly labeled in a controlled area; avoid smoking

$$\frac{\text{NOEL or NOAEL} \times 70 \text{ (50) kg (average worker weight)}}{\text{serum half-life} \times \% \text{ absorption} \times \text{respiration over an 8-hr workday} \times \text{safety factor}}$$

OCCUPATIONAL EXPOSURE LEVELS

The so-called Occupational Exposure Level (OEL) is a key parameter for people responsible for the safety issues in pharmaceutical and chemical industries.^[13,14] The assessment and the application of the OEL are particularly important also for hazardous pharmaceuticals that are routinely handled within the pharmaceutical companies. There are different approaches to determine the OEL of a certain chemical and its relation to the handling/use of the substance. We are oriented to applying a tiered approach, which assesses all possible parameters that compose the hazard evaluation of a chemical substance.

Such a tiered approach is carried out in different phases:

Phase I: Identify NOEL–NOAEL in animal studies and also the possible effects in healthy human beings; kinetics/absorption data are also important.

Phase II: Find out all occupational toxicology data from available sources, treating the route of exposure as highly significant.

Phase III: Identify available epidemiological data (post-marketing surveillance and industrial hygiene).

Phase IV: Apply suitable and good safety factors.

Phase V: Calculate OEL using the following formula: (see equation above).

The final calculated value of the OEL will be considered during all procedures involving the chemical, in particular the possible human exposure consequent to its handling and use.

CONCLUSION

As we realize from the information provided in this article, the handling of hazardous chemicals and pharmaceuticals is a process involving many different areas of expertise. A company that intends to adopt a serious policy concerning the safety of their compounds (raw materials, intermediates, or bulks/API) needs to set up a multidisciplinary team with experts in pharmacology (for efficacy and epidemiology data), industrial toxicology (for classification), medicine (in relation to health), and management (in relation to legal responsibility in case of accidents). The key area is clearly industrial toxicology because of its capacity to interpret toxicological data de-

rived from various experimental activities and its use for safety. The presence of an industrial toxicologist is common in large organizations, but infrequent in small/medium companies where safety issues will become a problem in the near future.

The last step that is becoming more and more requested by competent authorities in terms of chemical safety is the preparation of a final RA on the basis of the intrinsic hazard features of the studied chemical, its use, and its possible exposure to humans. The final RA evaluation will give us the index of possible risk for humans and the containment measures to be adopted when the risk is too high.

The handling of substances classified as highly toxic, highly sensitizing, carcinogenic, or affecting the reproductive system should be kept to a minimum and, in some cases, banned if replacement is possible.

INHALATION, DRY POWDER

Lynn Van Campen and
Geraldine Venthoye

Inhale Therapeutic Systems, Inc., San Carlos, California, U.S.A.

INTRODUCTION

Drug delivery to the lung has been historically aimed at controlling local respiratory disease where the central airways may be as suitable a target for drug deposition as the deeper lung. With little exception, currently marketed inhalation products provide therapy for asthma, chronic obstructive pulmonary disease (COPD), and bronchitis. More recently, however, there has been significant interest in using the lung, and in particular the deep lung alveolar surface, as a portal to the systemic circulation for drugs not readily administered orally. Therapeutic targets have therefore broadened substantially because pulmonary delivery is recognized for its potential to provide a noninvasive alternative to injection. New delivery systems capable of delivering drug in particles or droplets small enough to reach the peripheral or deep lung are under intense development to meet these new therapeutic targets.

Delivery of drugs to the lung depends on administration by any one of three methods: nebulizer, metered-dose inhaler (MDI), or dry powder inhaler (DPI). The nature of the drug substance and its therapeutic target may dictate which lung-delivery dosage form is more appropriate for the drug. Nebulization, for example, requires that the drug dissolve well in an aqueous medium at a concentration suitable for convenient dosing. Drugs developed as MDIs must dissolve or suspend well in a nonaqueous propellant medium at a concentration appropriate for doses metered in volumes generally less than 100 μl . For DPIs, the physical properties of the drug substance determine the ease with which processing will yield a stable powder that can be effectively aerosolized in milligram quantities by the inhaler device to deliver the proper drug dosage.

Nebulizers

Nebulizers have a long history in pulmonary delivery. Although generally effective, traditional nebulizer systems require lengthy (10–20 min) administration periods during which drug solution is delivered with relative inefficiency using an external power source. More convenient hand-held systems are currently in

development and offer the convenience of portability and metered-dose administration (1). Depending on drug solubility and dose, these systems may require multiple actuations to deliver an effective dose.

MDIs

Since the 1970s, MDIs have dominated inhalation delivery, especially in the United States. MDIs are more convenient to use than nebulizers, generally offering 100–300 metered doses per pocket-sized canister. Limitations to the reliability of their therapeutic effectiveness, however, typically arise from the need for the patient to coordinate MDI actuation with breath inhalation (2) and from the deposition of a sometimes significant amount of drug, driven by the propellant blast, to the back of the throat instead of the lung. Then, in the late 1980s, the chlorofluorocarbon (CFC) propellants used in MDIs were identified as agents contributing to the depletion of the ozone layer. This led to industry-wide reformulation efforts still underway to replace CFCs with environmentally more friendly propellants.

DPIs

The technical challenges of MDI reformulation have contributed to a growing interest in the potential of DPI technology for the development of new products that satisfy similar therapeutic, market, and environmental needs.

The DPI device presents medication to the patient as a dry powder in a form that can be inhaled orally for delivery to the target lung tissues. The delivery system should assist in the generation of very fine particulates of medication in a way that enables them to avoid the impaction barriers that normally operate in the lung to prevent the ingress of potentially harmful particles. These barriers include the oropharynx and, for deep lung delivery, the air-conducting bronchi and bronchioles.

Studies have shown that to clear the oropharyngeal impaction barrier (comprising the mouth, throat, and pharynx), particles with aerodynamic diameters smaller

than 5 μm are required (3, 4). Only particles with aerodynamic diameters less than 3 μm will reach the terminal bronchi and the alveoli in significant numbers (5). Therefore, the particle diameter required to be produced by the delivery system will depend to a great extent on the intended target lung tissue. Lung deposition is also affected substantially by the specific inhalation dynamics of the patient, which, in turn, are influenced by the delivery device. This article addresses various attributes of the dry powder inhalation product, from intrinsic material properties to final product performance.

More simple in concept than implementation, DPI technology is rapidly expanding to address a broadening therapeutic need as well as market opportunity. Characteristics of the ideal DPI system will include most or all of the following attributes:

- Simple and comfortable to use;
- Compact and economical to produce;
- Highly reproducible fine-particle dosing;
- Reproducible emitted dose;
- Physically and chemically stable powder;
- Minimal extrapulmonary loss of drug, with low oropharyngeal deposition, low device retention, and low exhaled loss;
- Multidose system;
- Powder protected from external environment and can be used in all climates and protected from moist exhaled air;
- Overdose protection; and
- Indicate number of doses delivered and/or remaining.

Outline

Fine particle powders can be produced by various methods such as micronization or spray drying. The physicochemical nature of these fine particles generally defines the stability of the bulk powder, which in turn is critical to the long-term effective performance of the dry powder product. The section *Fine Particles and the Solid State* is an introduction to better understanding the fundamental properties that underlie the behavior of bulk powders. Commentary on the various means of producing fine powders follows in the section *Powder Production: Formulation and Processing*.

Drug containment in DPIs falls into two categories: unit dose, in which the dose is premeasured during manufacture, and reservoir, in which the drug dose is metered during dose administration. Some devices store multiple unit doses for convenience. These are addressed in the section *Filling and Packaging*. The next section, *Devices: Forming the Dry Powder Aerosol*, considers the various

means of aerosolizing powder in the context of device design history and functionality. Advantages and disadvantages of different design types are considered.

Performance and Regulatory Requirements describes various ways of characterizing the dry powder aerosols and provides information on product quality performance requirements and how these attributes must be reflected in registration applications.

The Role of DPIs in Therapy briefly addresses factors affecting the therapeutic profiles of drugs delivered by DPI profiles. The article concludes with *DPIs: A Burgeoning Industry*, which surveys the DPI products on the market in 1999 and a selection of those known to be under development. Thoughts on the potential of the DPI dosage form in future therapeutic applications conclude the article.

FINE PARTICLES AND THE SOLID STATE

Crystalline and Amorphous (Glassy) States

Pharmaceutical solids can generally be described as either crystalline or amorphous (or glassy). In fact, the actual solid phase composition of a pharmaceutical formulation is usually characterized by an intermediate composition composed of both crystalline and amorphous character. In a multicomponent system such as a solid formulation comprising drug and excipient(s), certain components or even a single component may be amorphous. Because the amorphous form of a material is always a less stable, higher-energy form than its crystalline counterpart, the distinction between these forms relates to thermodynamic stability of the solid.

Crystalline materials are characterized by a three-dimensional, long-range order that translates into a distinct and unique molecular pattern that can be characterized by X-ray diffraction (XRD) (6). The molecular arrangement of the glassy state resembles that of the liquid state and lacks three-dimensional order. Thus, the classically glassy state has been designated as amorphous, that is, without structure. Pharmaceutical operations commonly used in the manufacture of DPI formulations, such as milling, spray drying, and lyophilization (freeze drying), produce materials possessing amorphous character (7).

Milling of crystalline materials introduces or increases amorphous character as the result of the significant mechanical activation that takes place during the process, including friction, deformation, attrition, and agglomeration (8). The extent of disorder, or amorphous character, introduced by the milling process depends on the behavior

of the material and its inherent resistance to the milling-imposed stresses, the amount of energy imposed by the process, and the time scale of energy release. Solid particles formed from the liquid phase, as in spray drying or freeze drying product from solution, are predominantly amorphous materials.

Crystalline materials exhibit a characteristic melting point at which they convert into a liquid form, whereas amorphous materials show no such defined transition. Rather, amorphous materials change on heating from a brittle glassy state to a rubbery state over a narrow temperature range known as the glass transition temperature, or T_g . Orders of magnitude of change in properties such as viscosity and molecular mobility take place near the T_g for amorphous materials; the temperature dependence of these properties near the T_g is typically non-Arrhenius (9). Glassy to rubbery transition is also associated with a stepwise change in the heat capacity. Thus, the T_g of an amorphous material may be determined using a differential scanning calorimeter where a stepwise change in heat flow (corresponding to a change in heat capacity) is observed during sample heating (10). For many hydrophilic drugs and excipients, water acts as a plasticizer, increases molecular mobility, and reduces the glass transition temperature. It is not uncommon for as little as 2–3 wt% water to depress the T_g by 30–40°C. The physical and chemical stability of a glassy material decreases as it approaches the T_g because of that mobility. Thus, the presence of water promotes instability. The rate at which a compound crystallizes from an amorphous state will likewise increase as the temperature of storage approaches T_g and as moisture content is increased (11, 12).

Effect of Physical State on Stability of Dry Powder Formulations

The impact of even subtle changes in physical properties of a DPI formulation can lead to substantial changes in aerosol behavior. Moisture uptake by the hydrophilic components of the formulation can lead to surface dissolution and liquid bridging between particles. This in turn leads to crystal growth, particle fusion, and an increase in particle size, which can result in strongly diminished aerosol performance (13). Powder densification under vibration during unit dose or reservoir filling, as well as product shipping, can also affect the observed aerosol behavior of dry powders.

Because of their greater molecular mobility in the solid state, amorphous systems generally exhibit greater physical and chemical instability at any given temperature

compared with their crystalline counterparts. Thus, DPI formulations are desirably prepared in a crystalline state. The low molecular weight of drugs in DPI products currently marketed supports their crystalline nature. Since the late 1980s, there has been increased interest in delivering drugs of biological origin, such as proteins for systemic uptake. These molecules typically do not crystallize and tend to remain amorphous. In freeze-dried and spray-dried biologicals for pulmonary delivery, excipients that act as protectants such as sugars must also remain amorphous to interact with the protein and/or provide a rigid matrix around the protein molecules to restrict and stabilize their motion. As with any amorphous product, physical change can be minimized by storage at temperatures well below the T_g and protection from moisture during handling and storage.

The chemical stability of an amorphous formulation also is usually a function of its storage temperature relative to T_g . The enhanced molecular mobility achieved near the glass transition translates into an increase in translational diffusion-dependent degradation pathways such as aggregation in proteins. It should be recognized that the reaction kinetics near the T_g do not obey Arrhenius kinetics and that extrapolation of the accelerated stability data generated near the T_g to stability at the storage temperature should be viewed with extreme caution. Amorphous materials must be stored well below the glass transition (at least 10°C and typically 40–50°C below T_g) to maintain their physical and chemical stability.

When dealing with partially crystalline materials such as those produced by milling, the impact of water uptake is exaggerated. The amorphous component likely absorbs greater quantities of water than its crystalline counterpart, leading to reduced T_g , increased molecular mobility and both physical and chemical instability.

Bulk Powder Properties

The respirable powders of a DPI cannot be characterized adequately by single particle studies alone; bulk properties must also be assessed because they contribute to ease of manufacture and affect maximal system performance. Primary bulk properties include particle size, particle size distribution, bulk density, and surface area. These properties, along with particle electrostatics, shape, surface morphology, etc., affect secondary bulk powder characteristics such as powder flow, handling, consolidation, and dispersibility.

The characterization and control of primary particle size and the particle size distribution of drug-containing particles are perhaps the most important factors in the

design and manufacture of dry powders for inhalation. The size, density, and shape of a particle determine its aerodynamic behavior and therefore its likelihood of depositing in the desired region of the lung. The mean (average) or median (50th percentile) particle size may be based on the number of particles, the mass (or volume) of particles, or even the surface area of particles. The particle size distribution describes the range or frequency of particle sizes occurring in a sample or the width of the particle size distribution in a sample. The variation in these size parameters owing to sampling errors must be considered in characterizing blended powders, powders stored for prolonged periods, or powders that have been mechanically agitated.

Mass median diameter (MMD) is the most common descriptor of primary particle size and may be determined by sieving or centrifugal sedimentation. Volume median diameter, as determined by laser diffraction, may be used as an approximation of MMD provided the particle density is known and does not vary with size and the particle shape is near spherical. The MMD of a powder can be used as a predictor of aerodynamic diameter by:

$$\text{MMAD} = \text{MMD} \cdot \rho_{\text{true}}^{1/2}$$

where MMAD is the mass median aerodynamic diameter, and ρ_{true} is the true density of the particle, usually determined by helium pycnometry. Cohesion/adhesion between particles normally results in the MMAD being larger than predicted. Values of MMAD less than 5 μm are considered necessary to facilitate airborne particle transit past the larynx and deposition within the lung. Powders intended for delivery to the deep lung, such as treatments for asthma or for systemic delivery, require aerodynamic behavior reflected by MMAD values between 1 and 3 μm (14). Particles of MMAD less than approximately 0.5 μm are likely to be exhaled.

Surface area is a bulk powder characteristic directly dependent on particle size distribution, porosity, and morphology. It is commonly determined by nitrogen adsorption, whereby the adsorption isotherm data are fit to a suitable mathematical model from which surface area is derived. If the particle size distribution is sufficiently narrow and the particles are not hollow or porous, the surface area can be used as a measure of change in average particle rugosity or shape. Surface area may be a more sensitive means of monitoring process control during fine particle manufacturing (jet milling or spray drying) than are particle sizing techniques.

Bulk powder density, porosity, and consolidation rate are used as characteristics of powder structure and ease of flow. These properties are typically more difficult to

determine for fine respirable powders than for coarse particles owing to the formation of bridging structures caused by high interparticulate interaction. These forces must be overcome by introducing energy, such as ultrasonic vibration or mechanical agitation, to fluidize micron-sized powders in a controllable manner. Carrier-based powder formulations are designed in part to overcome the inherent cohesion of micron-sized particles. In these formulations, the microfine drug adheres to larger carrier particles, improving powder flow and metering capability. For effective delivery, the drug particles must, of course, separate from their carrier on aerosolization and/or inhalation.

Pelletization is often used to improve the flow properties of micron-sized powders. Pelletization converts an ensemble of single particles into larger agglomerates through the formation of weak solid bridges between particles. This process also results in increased bulk powder density (ρ_{bulk}). The solid bridges formed during pelletization may aid powder flow and metering but must be overcome during aerosolization (15).

Bulk powder density must be distinguished clearly from the true density of particles. Bulk powder density is simply the mass of a powder bed divided by its volume. The volume of the powder bed includes the spaces between agglomerates, between primary particles, and the volume of micropores within the particles. These voids within the powder bed volume are collectively the powder porosity. Powder porosity (F) is calculated as:

$$F = (1 - \rho_{\text{true}}/\rho_{\text{bulk}})$$

The average number of contact points between particles increases as bulk density increases, and the interparticulate forces at these contact points must be overcome to produce a dispersed aerosol cloud. Therefore, a powder of low bulk density may be more easily dispersed as an aerosol than an otherwise identical powder of high bulk density.

However, a powder with low bulk density may be more prone to consolidation than a powder with high bulk density. Powder consolidation can be envisioned as a process of densification or packing of the particles. Consolidation occurs most rapidly during the powder agitation that accompanies powder filling or product shipping; even the imperceptible vibrations a powder experiences during seemingly static storage cause consolidation with time. The rate and extent of consolidation are dependent on particle size distribution and particle shape and can be used to describe the dynamic behavior of powder structures. The extent of powder consolidation, or compressibility, can be

evaluated by performing tap density measurements, and using the following relationship:

$$100 \times (\rho_{\text{tap}} - \rho_{\text{aerated}}) / \rho_{\text{tap}} = \% \text{ compressibility}$$

where ρ_{tap} is the tapped bulk density, and ρ_{aerated} is the aerated bulk density.

An understanding of the behavior of a powder during the manufacturing process, e.g., during blending, may aid in the identification of an optimal filling and packaging process. Blended powders may also undergo segregation of active particles from carrier particles concurrently with consolidation. Although segregation can lead to poor drug content uniformity, it is in fact desirable in the case of aerosolizing a powder composed of drug blended with a larger particle size carrier.

POWDER PRODUCTION: FORMULATION AND PROCESSING

The primary factor influencing the manufacture of DPI powders is the need to produce material that can penetrate into the lung. The manufacturing of fine particles is challenging, especially with regard to reproducibility. This challenge has resulted in the development of various approaches to the controlled production of fine particles, primarily depending on the nature of the drug. Of the processes described later, micronization and blending and, more recently, spray drying are used most often.

Once manufactured, small particles present another challenge. At small particle diameters, gravity ceases to be the major force exerted on the particles, and instead, interparticle forces become more prominent. The resultant increase in the cohesive and adhesive nature of the particles produces problems such as poor flowability, fillability, and dispersibility. These problems are typically minimized by blending with larger, less cohesive excipient particles such as lactose or pelletization of the individual drug particles. The cohesive nature of particles can be reduced further by modifying the particle surface, the goal of several emerging technologies.

Secondary processing techniques are often employed in powder production to ensure that the stability of the manufactured drug product is ensured. These major technologies are addressed in more detail later.

Formulation

Formulation of dry powders for inhalation must rely on a very short list of excipients to fulfill the customary roles of diluent, stabilizer, solubilizer, processing aid, and property

modifier (e.g., flow sustain release agent). Only a few materials are approved in the United States for use in inhalation products, and of those (e.g., propellants, surfactants), many are of little help in dry powder formulation.

Where dose requirements and drug properties allow, drug may be processed in the absence of any excipient, e.g., Astra's Pulmicort Turbuhaler. Most DPIs marketed or under development, however, rely on the addition of lactose as filler and flow enhancer (see *Blending*). Given the proprietary nature of product development, it is not known what additional excipient materials will immerge in the future as safe for inhalation. It is likely, however, that the expansion of inhalation technology to systemic delivery will call for the addition of sugars, buffer salts, and other excipients common to parenteral dosage forms to the list of acceptable inhalation excipients.

Controlled Crystallization or Precipitation

Crystallization, or precipitation, is the process by which particles are produced from solution of the material in a suitable solvent. The level of control over this process determines the physical nature and size of the finished particles. Most pharmaceutical bulk material is produced through crystallization as the final stage of the manufacturing process. The formation of a stable, crystalline material is normally the target of this final step.

In the production of materials for use in DPI products, however, the particle size of the crystallized product is normally too large. Subsequent reduction in particle size is then necessary and can significantly alter the physical nature of the material (16).

Micronization

Micronization is a high-energy particle-size reduction technique that can convert coarse-diameter particles into particles of less than 5 μm in diameter. Different types of equipment can micronize particles, for example, jet or fluid energy mills and ball mills. Although the different equipment have different operating parameters, the fundamental method of reducing the particle size is the same. All techniques involve applying a force on the particle, typically in the form of a collision, either particle–particle or particle–equipment. The force acts at imperfections in the crystal surface, initiating crack propagation through the particle. As the size of the particle decreases, the number of imperfections decreases, thereby making the task of reducing particle size more difficult.

Micronization has been used for the past 50 years to produce small particles for inhalation therapy. However, only in recent years have batch-to-batch reproducibility and stability problems been associated with the technique. Batch-to-batch variations can be caused by morphological differences in starting material; thus, it is critical that a reproducible raw material supply be available. Stability issues typically derive from changes to the varying quantities of amorphous material that are produced by the micronizing process on the surface of the resulting particles (17). This can be minimized through careful control of the micronization process, including processing conditions, batch size, and feed rate, or by the addition of a secondary processing procedure. In addition, micronization can cause decomposition of some materials (18). The issues associated with micronization are forcing many companies to investigate alternative methods of producing small particles.

Blending

The most commonly used method for improving the flowability, fillability, and dispersibility of small cohesive particles is blending the drug with excipient particles, most commonly lactose, of considerably larger particle size. Typically, these large excipient particles are greater than 60 μm , and the small drug particles are less than 5 μm . The objective of the mixing process is to produce an ordered powder in which the small particles attach themselves to the surface of larger “carrier” particles. The challenge is to ensure that the force of adhesion between the drug and carrier is strong enough to withstand segregation during blending and product storage and weak enough to allow separation of the drug particles from the carrier surface on aerosolization (19, 20). During formulation feasibility, the blends are made by mortar and pestle and/or geometric mixing in a tumbling blender. For high-volume production, the process generally involves a high-shear mixer.

The final product performance of a powder blend in a DPI is ultimately dependent on the individual drug and carrier properties as well on the process by which they are blended (21, 22). Small changes in carrier morphology can result in significant variations in the dose received by a patient (16). Again, control of the raw material supply is critical to successful product development. Moreover, secondary processing may be required to ensure that carrier particles behave consistently from batch to batch. Steps that involve transport or storage of the finished blend should be monitored closely to avoid segregation, which occurs when the drug separates from the carrier or when

carriers of different sizes separate. Segregation can be minimized by the careful selection of formulation and process equipment. For example, hopper design can play a significant role in minimizing segregation.

Pelletization

Pelletization, which often does not require the use of excipients, may offer an alternative to blending for high-dose therapeutics. The process involves deliberate agglomeration of the fine drug material into less cohesive, larger units (23). Pelletization is usually achieved by vibratory sieving or any process that tumbles powder. All processes require particular attention to time and energy parameters to ensure a consistent product. The resultant pellets must be used in a system capable of deaggregating to an appropriate particle size for aerosol drug delivery (15).

Secondary Processing

As discussed, materials used in dry powder inhalation are predominantly crystalline in nature, with varying degrees of amorphicity. This typically results from the high-energy milling process, which introduces regions of amorphous material within a crystalline material. Occasionally, however, the converse is true. Minimizing any change over time and ensuring that the material is physically stable before final packaging are major formulation challenges. These stability issues tend to be physical in nature, but occasionally chemical changes such as impurity formation also occur.

The technique generally used to minimize the degree of change in crystallinity of the milled product is to eliminate the water or other solvents from the product, usually by packaging the material within a suitable barrier (for example, aluminum foil laminate). Other techniques include the production of a 100% crystalline material, which may eliminate the effects of moisture. This technique, however, may require a secondary production stage of annealing or a quarantine period to allow the product to equilibrate under controlled storage conditions.

The final measure of crystallization effects is assessed by appropriate rigorous stability data [for example, 6 months accelerated stability at 40°C/75% relative humidity (RH)]. This may seem excessive, but measuring the degree of crystallinity is inherently difficult because of low analytical sensitivity (for example, amorphous components below 5 wt%), and pure single-phase standards are difficult to prepare and, subsequently, to measure.

Spray Drying

Spray drying, a process typically used in the production of coarser (up to 500 μm) food, pharmaceutical, and industrial powders, can also be used to prepare microparticulate powders for DPIs (13, 24–26). A typical first step involves creating a solution of the excipients and drug. Dissolving the excipients and drug ensures a uniform distribution of all the excipients and the active drug in the finished powder in contrast to the heterogeneous nature of blended powders. The solution is then atomized and mixed with a drying medium, usually air, or an inert gas if the feed consists of an organic solvent. The solvent is evaporated and removed from the drug solids.

Each spray-dried droplet forms a single particle whose size is determined by the droplet size, the dissolved solids of the feed solution, and the density of the resulting solid particle. For a given formulation and process, both the solid content and density of the powder remain constant within a batch and from batch to batch. Therefore, the distribution of the primary particle size is determined by the droplet size distribution. A narrowly distributed particle size can be achieved with a well-designed atomizer and well-controlled atomizer process parameters.

The droplet has a relatively short residence time (on the order of seconds) in the spray dryer, which minimizes the degradation of heat-sensitive components. In addition, the drug is exposed to a temperature much lower than that at the drying inlet owing to the cooling effect of the solvent evaporation. Control of droplet residence time and the lower temperature defines the amorphous versus crystalline nature of the material.

A spray dryer consists of a feed tank, a rotary or nozzle atomizer, an air heater, a drying chamber, and a cyclone to separate the powder from the air. A rotary atomizer uses centrifugal energy to form the droplet. Pressure nozzle atomizers feed solution to a nozzle under pressure, which forms the droplet. Two fluid nozzles feed solution separately into a nozzle head, which produces high-speed atomizing air that breaks the solution into tiny droplets. Both the feed solution and the drying air are fed into the drying chamber in a standard cocurrent flow (27).

Lyophilization

Lyophilization, although a relatively expensive process, can be a good process for relatively unstable compounds. In lyophilization, the solvent (usually water) is frozen and then removed by sublimation in a vacuum environment. The low temperature maintained

during the entire process minimizes thermal degradation of the drug compound.

Typically, the drying process can be divided into primary and secondary phases. During the primary phase, the drug solution is filled into vials and then placed within a temperature-controlled drying chamber. There, the solution is frozen according to physiochemical principles as the shelf temperature is lowered to below freezing. The shelf temperature is subsequently increased but maintained below the freezing point. A vacuum is applied to the chamber to sublimate the solvent. This phase of the drying process extracts the majority of the solvent (50–80%).

During the secondary drying phase, the remainder of the solvent is removed at an elevated but still subfreezing temperature. During freezing, supercooling is necessary to encourage crystallization of the drug compound. The extent to which the compound is supercooled depends on the nature of the compound, the temperature program of the shelf, the heat transfer properties of the container, and the presence of particulates in the solution. The degree of supercooling determines the size of the solvent crystal and, subsequently, the size of the channel formed during primary drying. Consequently, the degree of supercooling affects the rate of sublimation, the rate of secondary drying, and, eventually, the surface area of the finished powder. A goal of secondary drying is to minimize product moisture content.

Therefore, it is most important to select a cooling temperature profile to achieve the desired objective(s). The objective could be simply to achieve a uniform degree of supercooling and freezing or to add an annealing process to allow the solute to crystallize or the ice crystal to grow. The possibility of allowing a long annealing process gives great flexibility to achieve the desired solid-state property for the powder.

The lyophilized cake must then be milled. Compared with particles generated by spray drying, the particle size of milled lyophilized powders generally has a broader distribution than does spray-dried powder, which is formed one particle at a time in a continuous process. Despite the longer processing time necessary to create a dry powder through lyophilization (and the consequent economic implications), this process can provide the formulator with better control of the powder in its solid state.

Supercritical Fluid Technology

Extraction by supercritical fluids, carbon dioxide and propane in particular, is currently being investigated as a means of controlling the size and shape of particles

for inhalation. Supercritical fluids are liquids above their critical pressure and temperature (28). Under these conditions, the molecules exhibit the flow, polarity, and solvency properties common of liquids but have the diffusivities and reactivities characteristic of gases.

Precipitation of the particles occurs by two methods involving atomization of a feed: 1) rapid expansion of supercritical solutions containing dissolved drug, and 2) gas antisolvent recrystallization, the supercritical fluid acting as an antisolvent for dissolved drug contained in droplets of another miscible or partially miscible liquid (for example, ethanol, methanol, and acetone).

The second technique, sometimes described as SEDS (solution-enhanced dispersion by supercritical fluids), has been scaled up successfully for an inhalation application to pilot plant manufacture. As with spray drying, this technique is a single-step process. The drug material must show solvency in the cosolvent but complete insolubility in the supercritical carbon dioxide. The resultant solvent-free particles are less cohesive than micronized material as high crystallinity is achieved, leading to decreased charging effects (29). Particle size distributions for these powders are reported to be narrow, with small median aerodynamic diameters ($<2.5\ \mu\text{m}$). In addition, regular particle morphologies are obtained for these thermodynamically stable powders, making them amenable to further processing steps and handling (30).

FILLING AND PACKAGING

The primary consideration when developing systems for packaging dry powders for dose delivery is the goal of delivering the correct drug dosage to the patient. When dealing with drug powders intended for use in DPIs, some basic issues must be considered—specifically, that the drug usually must be delivered in a small volume, which is often difficult to handle owing to small particle size.

The greatest challenge faced in developing packaging systems for dry powders relate to maintaining dispersibility in packaging, which can be affected by compression and electrical charge. Compression of the drug powder, which can be a consequence of excessive handling, can result in an unintended increase in drug concentration. The small drug particles are also vulnerable to alteration in electrical charge, which can result from the motion of particles, against both themselves and the packaging equipment, and from the unintended absorption of water by the drug powder.

Package dose metering can be accomplished by weight or by volume. Dry powders developed for DPIs are formulated to deliver a specific dose of drug per a given unit of drug powder. Drug powders can be packaged either in unit dose or in reservoir systems, each of which has certain advantages (Table 1).

Unit-Dose Systems

Unit-dose systems package drug powders into individual-use packages that contain a known quantity of drug. Patients may use single or multiple units of the drug to obtain a given dose. The greatest advantage of unit-dose systems is that a greater degree of control at the manufacturing level can be maintained. Individual drug doses can be metered by weight or volume. Although metering by weight results in a high degree of accuracy, it is a slow process. Thus, more commonly, unit-dose packaging is metered by volume.

Metering by volume, although offering a reliable means for high-volume production, has disadvantages related to the dispersibility of the drug powder, which in turn can affect the accuracy and precision of the drug dose. Dispersibility can be managed by devising filling processes that optimize powder flow, which will vary by drug compound; by minimizing handling and thereby compression of the drug powder; and by minimizing the relative motion of drug particles against other drug particles and against the filling equipment. Minimizing drug powder motion can reduce electrostatic charging of particles and consequent equipment malfunctions and problems with packaging, which include dose-extraction difficulties and particle dispersion at the time of drug administration.

Unit-dose systems typically rely on blister packaging or capsules to contain the drug until it is dispersed by the delivery device. Blister packages have several advantages over capsules. Those constructed of aluminum are generally impervious to moisture. Inner linings of either polyvinyl chloride or polypropylene create means for sealing the package. Gelatin capsules generally contain approximately 12% water under ambient conditions and thus are a potential source of moisture to powder not equilibrated to ambient relative humidities.

Reservoir Systems

Reservoir systems offer the advantage of variable dosing, generate less waste, are less expensive to manufacture, and are simpler to use than unit-dose systems. Relying on a metering system contained within the delivery device, they

Table 1 Primary packaging for DPI drug formulation

Dosing system	Advantages	Disadvantages
Unit-dose	Simpler, cheaper device, less prone to malfunction Protects powder up to the time when it will be delivered to the patient as an aerosol	Patient must handle and load individual unit-dose packages into the device before dosing Dose titration is limited to dose-quantity available from drug supplier (similar to pills)
Multidose	More convenient for the patient	The device becomes more complex because means to load multiple doses are required Also, means for displaying number of doses left are required Device may be more prone to malfunction owing to jamming or improper indexing
Reservoir	Multidose and dose titration easy to implement Convenient—no separate unit-dose blisters to worry about	Powder not generally well protected after reservoir is opened; physical and/or chemical characteristics may deteriorate with time Biological contamination may be an issue Metering of the dose is carried out by the device, which increases the device complexity; metering often is not adequately controlled because the physical characteristics of the powder are often unknown at the time of dosing

may be less precise in their drug delivery. Because the drug reservoir must be accessed repeatedly, these systems encounter an increased difficulty in maintaining moisture level. Maintaining a highly flowable drug powder in this system may also lead to greater drug formulation challenges.

DEVICES: FORMING THE DRY POWDER AEROSOL

Design Objectives and Constraints

The ultimate goal of all pulmonary delivery devices is to reproducibly deposit the required quantity of drug in the target lung tissues. Many factors influence the selection of a particular DPI design, including the characteristics of the drug to be delivered, its powder formulation, and its associated therapeutic regime. Other factors that must be considered include drug cost, desired dose, market factors, and expected degree of patient compliance.

Drug cost plays an important role in determining the economic feasibility of a device by determining how much of a drug may be lost in administration and routine device use. Drug dose and side effects may determine the reproducibility bounds of particle size and mass of drug delivered that are necessary for effective

therapy. The drug target tissue may determine the importance of achieving a very small particle size; local delivery of drugs to the upper airway may allow for a larger particle size than delivery of particles to the deep lung for systemic absorption. The degree of cohesive-ness of the powder particles will determine how much energy the device must transfer to produce a particle of a given size. The therapeutic regime and a range of market factors, such as degree of convenience and cost of other available drugs and/or therapies, may determine how portable or inexpensive the device must be. The anticipated degree of patient compliance may favor some technological solutions over others.

DPIs cannot be considered devices alone but must be considered as components of a larger delivery system, which also includes the formulation of the drug powder, its manufacturing processes, and packaging.

Functional Description

Several DPI designs have been proposed, developed, and successfully marketed in the past 3 decades. Although these devices vary widely in characteristics and operation, they all perform certain basic functions. A DPI must extract the dose from the bulk powder drug package, generate a fine cloud of drug particles by deagglomerating the powder and diluting it with air, and deliver the drug cloud to the patients' airways.

Bulk Powder Drug Package

The first task for a device in delivering a dose is extracting the dose from the drug package. As addressed earlier, two primary alternatives are available: 1) a number of doses may be stored in a powder reservoir, and 2) each dose may be individually packaged as a unit dose. Reservoir systems are inherently multidose. With unit-dose systems, the device may require individual loading of a unit-dose package before inhalation or loading of several unit-dose packages into the device for multidosing.

Energy Sources

Energy input is required to extract the powder from its packaging, generate the fine particle cloud, and dilute it with air. Historically, this energy comes from the patient’s inhalation effort (Table 2). In some cases, the energy for extracting/metering the powder comes from the mechanical manipulation of the device by the patient (31, 32). More recent designs use concepts borrowed from the MDI industry or novel approaches involving other technologies.

Uncontrolled vs. on-demand aerosol generation

DPI devices that rely on patient inhalation are inherently on-demand, that is, only when the patient inhales is the aerosol delivered. In contrast, MDIs are inherently uncontrolled, and the patient’s breathing maneuver has to be carefully synchronized to the aerosol generation event for effective dosing (Table 3).

DPI devices that rely on sources of energy other than patient inhalation effort may face similar problems as MDIs. Devices may “trigger” the aerosol generation event, which then follows uncontrollably. Alternatively, the

delivery of energy to the powder may be modulated by the device and controlled based on monitoring of the patient inhalation maneuver. Table 3 gives some advantages and disadvantages to both approaches.

Homogeneous Powders and Blends

Dry powders must be able to flow readily to leave the capsule or powder reservoir but also must generate a fine aerosol so that the patient can inhale a proper dose. These two requirements are often difficult to achieve simultaneously. Fine powders tend to be cohesive and have poor flow properties. Blending with a carrier phase, pelletization, and other approaches have been used to overcome these limitations. The use of blends and homogeneous powders is compared in Table 4 from a DPI device perspective.

PERFORMANCE AND REGULATORY REQUIREMENTS FOR DPIS

Performance Characterization

Two critical attributes characterize the performance of DPIS: the uniformity of the delivered dose and the aerodynamic assessment of particle size distribution. To determine delivered-dose uniformity, an apparatus capable of quantitatively retaining the delivered dose leaving the device is used. For aerodynamic particle size assessment, a multistage liquid impinger or cascade impactor is used. All aerosol performance testing must be conducted under defined temperature and humidity conditions.

Table 2 Energy sources for delivery

Patient inhalation		Other (air pump, metered propellant, electrical, other)	
Advantages	Disadvantages	Advantages	Disadvantages
No need to coordinate aerosol generation with patient inhalation	Delivery, dispersion performance and thus dose is affected by the patient’s ability to inhale at a suitable high flow rate	Decouples aerosol generation from patient ability to perform a correct inhalation maneuver	Adds complexity and cost to the device by increasing the number of subsystems in it
Device is generally very simple in many cases, no moving parts are involved in powder deagglomeration		Allows the extraction and deagglomeration of more cohesive powders because additional energy can be applied in the process	

Performance Specifications

Currently, the United States, European, and British pharmacopoeias specify different requirements for delivered-dose uniformity. Table 5 details these requirements as well as proposed U.S. Food and Drug Administration (FDA) expectations (33). The *Japanese Pharmacopoeia* does not specify a delivered-dose uniformity requirement. Current compendia should be consulted as references.

Of the four pharmacopoeias, the *U.S. Pharmacopeia* (USP) has the strictest requirements for delivered-dose uniformity. Although the *British Pharmacopoeia* (BP) allows the same performance range, the USP defines the range around the label claim, and the BP defines the range around the average value. FDA expectations for delivered-dose uniformity is currently tighter than those specified in all the pharmacopoeias.

The various pharmacopoeias outline appropriate methods for aerodynamic assessment of particle size distribution. The USP defines the size distribution through mass median aerodynamic diameter (MMAD) and geometric standard deviation (GSD). None of the pharmacopoeias specify a requirement for particle size. However, the particle size specifications that are set should be appropriate for the intended use of the product. For example, if the particles are intended to reach the deep lung, the MMAD of particles exiting the device should be less than 5 μm . In general, the smaller the aerosol MMAD, the greater the deposition in the lung.

Two recent trends originating with the FDA may influence the assessment and reporting of aerodynamic

particle size distribution. The first is determining the particle size distribution from a single or unit-emitted dose. This may pose an analytical challenge in some cases because the amount of active ingredient in each stage may be present only in trace amounts. The second is setting a drug quantity specification for each stage of the impinger or cascade impactor.

RELEASE AND STABILITY TESTING PARAMETERS

Various dry powder attributes are assessed at release and on stability. These include physical characteristics such as powder appearance, content uniformity, delivered dose uniformity, and particle size distribution. Chemical attributes that may be assessed include drug content, purity, and identity as well as the water content of a powder. Dry powders may also undergo microscopic evaluation for foreign particulate matter, unusual agglomeration, and particle size. Microbial limits also should be examined, including the total aerobic, yeast, and mold counts. The presence of specific pathogens should be ruled out. The dry powders also may be dissolved to test for pH level. In addition, certain compendial requirements for content and delivered-dose uniformity should also be measured.

The USP and *European Pharmacopoeia* (EP) propose that the total aerobic count not exceed 100 CFU/g, that the total yeast count and mold count not exceed 10 CFU/g, and that no specific pathogens be detectable. Specifications for the other attributes should be based on the intended use

Table 3 Control of aerosol generation

Uncontrolled		On-demand	
Advantages	Disadvantages	Advantages	Disadvantages
Device is simpler; no feed-back systems are required to monitor the patient.	More prone to patient misuse	Aerosol is delivered when patient can inhale it most effectively	Device is more complex because feed-back systems (mechanical or electronic) are required
“Violent” aerosol generation processes are allowable, permitting the delivery of large amounts of energy to the powder in a very short period of time	Typically requires the use of a holding chamber to store the aerosol in between generation and patient inhalation, resulting in a larger-size device	Better dose control	Energy delivery to the powder has to be very well-controlled
			Device may be more prone to failure

Table 4 Influence of powder behavior on device design

Blends (lactose carrier)		Homogeneous powders	
Advantages	Disadvantages	Advantages	Disadvantages
Powder can be easily extracted from its packaging	On delivery, coughing and other unpleasant sensations may be induced because the carrier particles deposit in the mouth and throat	Little mouth and throat deposition; patient does not “feel” he/she is inhaling an aerosol	Formulation process becomes a key factor in the development of the product; the properties of the compound to be delivered dominate the performance of the resulting powder
Inclusion of the carrier phase usually facilitates dispersion	A larger amount of powder needs to be moved and dispersed; in terms of energy requirements, unit dispersion may be offset by the increase in payload		

and the historical performance of the product. As with other dosage forms, specifications must be met throughout the intended shelf life of the product.

The International Conference on Harmonization (ICH) has identified stability requirements for room temperature storage and testing intervals. It recommends that dry powders be stored at 25°C and 60% RH for real-time conditions; at 40°C and 75% RH for accelerated conditions; and 30°C and 60% RH if significant change is observed at accelerated conditions. The ICH recommends testing samples every 3 months for the first year, every 6 months for the second year, and yearly thereafter. In addition to these requirements, the FDA suggests a storage condition at 25°C and 75% RH if significant change is observed at the accelerated condition. Six-month data would be required at the time of the New Drug Application (NDA) submission, and the study must cover 1 year.

When an NDA is submitted, the FDA requires that 12 months of data be collected at real-time conditions and 6 months of data be collected under accelerated conditions. If significant change is observed at 6 months for the accelerated condition, 6-month data at the 30°C and 60% RH condition must be submitted, and the study must cover 1 year.

ROLE OF DPIS IN THERAPY

Some direct comparisons of DPI and MDI for the same drug have been made in the interest of developing alternative but comparable products for patients. The therapeutic performance of inhalation delivery systems is

as dependent on the patient as it is on the product itself. Therefore, some demonstration of clinical comparability is generally required to support product substitution.

The deposition pattern of the inhaled dry powder aerosol can be strongly influenced by the patient's inhalation dynamics and lung anatomy. At high inhalation flow rates, a given particle will have a greater tendency to impact the back of the throat or to deposit in the upper airways. For those delivery systems requiring high flow to deaggregate the powder particles, deep lung deposition is less accessible. The proliferation of device designs has been in part the result of attempts to minimize dosing variability regardless of source (34).

The target for lung deposition varies depending on the therapy under consideration. In the treatment of asthma by β -adrenergic agonists, the Central airways are generally targeted. On the other hand, therapies intended to treat alveolar disease, chronic obstructive pulmonary disease, or systemic conditions must reach the peripheral regions of the deep lung.

Among the pharmacokinetic advantages offered by delivery to the lung are fast onset of action and lack of first-pass effect. Doses to the lung can prove 10–20 times more effective than oral dosing and for local therapy can result in substantially reduced side effects.

In a study, three different fluticasone propionate products—an MDI and two DPI products, Diskhaler and Diskus—were directly compared in healthy volunteers and patients (35). The systemic drug bioavailability was highest for the MDI, whereas the bioavailability was similar for the two DPIs. The pharmacokinetic results are consistent with the in vitro evaluation in which the MDI gave the highest fine particle dose (FPD), whereas the two

Table 5 Product quality requirements

Pharmacopoeia	First-stage testing (N = 10)	Second-stage testing (additional 20)
United States	NMT (Not more than) 1 of 10 outside the range of 75.0–125.0% of label claim None outside the range of 65.0–135.0% of label claim; if 2–3 are outside of 75.0–125.0% and none are outside of 65.0–135.0% proceed to second stage	NMT 3 of 30 outside the range of 75.0–125.0% of label claim; none outside the range of 65.0–135.0% of label claim
British	NMT 1 of 10 outside the range of 75–125% of average value None outside the range of 65–135% of average value; if 2–3 are outside of 75–125% and none are outside of 65–135%, proceed to second stage	NMT 3 of 30 outside the range of 75–125% of average value; none outside the range of 65–135% of average value
European	NMT 1 of 10 outside the range of 65–135% of average value; none outside the range of 50–150% of average value If 2–3 are outside of 65–135% and none are outside of 50–150%, proceed to second stage	NMT 3 of 30 outside the range of 65–135% of average value; none outside the range of 50–150% of average value
FDA, proposed ^a	NMT 1 of 10 outside the range of 80–120% of label claim None outside the range of 75–125% of label claim; if 2–3 are outside of 80–120% and none are outside of 75–125%, proceed to second stage	NMT 3 of 30 outside the range of 80–120% of label claim; none outside the range of 75–125% of label claim
Japan	No delivered-dose uniformity specification	N/A

Table 6 Earliest dry powder inhalation systems

Year introduced	Name	Manufacturer	Indication	Packaging/ metering	Energy source(s)	Blend
1949	Aerohaler	Abbott	Asthma, COPD	Unit dose; “sifter” cartridge	Mechanical, patient inspiration	No
1971	Spinhaler	Fisons (now Aventis)	Asthma, COPD	Unit dose; hard gelatin capsule	Mechanical, patient inspiration	Yes
1977	Rotahaler	Allen and Hanburys (now Glaxo)	Asthma, COPD	Unit dose; hard gelatin capsule	Mechanical, patient inspiration	Yes
1988	Turbuhaler	Astra	Asthma, COPD	Reservoir	Mechanical, patient inspiration	No
	Diskhaler	Allen and Hanburys (now Glaxo)	Asthma, COPD	Multidose blister	Mechanical, patient inspiration	Yes
	Inhalator	Boehringer–Ingelheim	Asthma, COPD	Unit dose; hard gelatin capsule	Mechanical, patient inspiration	Yes

Table 7 More recent dry powder inhalation systems^a

Name	Manufacturer	Packaging/metering	Energy source(s)
Pulvinal	Chiesi	Reservoir	Mechanical, patient inspiration
Easyhaler	Orion	Reservoir	Mechanical, patient inspiration
Clickhaler	ML Labs	Reservoir	Mechanical, patient inspiration
Discus	Glaxo	Multidose blister	Mechanical, patient inspiration
Monohaler	Astra	Unit dose	Mechanical, patient inspiration
AIR ^b	Alkermes	Unit dose	Mechanical, patient inspiration
Spiros ^b	Dura	Multidose blisters	Mechanical, not driven by patient inspiration
Inhance TM Pulmonary Delivery System	Inhale	Unit dose	Mechanical, not driven by patient inspiration

^aThis list is not exhaustive. Many other manufacturers, in both the United States and Europe, are also developing dry powder inhalation drug-delivery systems.

^bIn clinical trials; not yet on the market.

DPIs had similar FPD values. It was also reported that in a separate study using healthy volunteers, the pharmacokinetics of a nonchlorofluorocarbon formulation have been shown to be similar to that for the original chlorofluorocarbon formulation for a fluticasone propionate MDI product. Consistent with their similar pharmacokinetic results, the clinical performance of Diskhaler and Diskus is similar in both children and adults (36, 37).

DPIs: A BURGEONING INDUSTRY

The first commercially available DPI system appeared on the market in 1949, developed and marketed by Abbott

under the name Aerohaler. Like all pulmonary drug-delivery methods that existed before now, it delivered small molecule compounds (bronchodilators or inhaled corticosteroids) to the airway (not necessarily to the deep lung) for the treatment of asthma or chronic obstructive pulmonary disease. Table 6 lists some of the early DPI systems and their basic characteristics.

Table 7 presents some of the newer entrants in the DPI field, most still focusing on local delivery of small molecule drugs to the airway for asthma or COPD but some in clinical trials for systemic delivery of macromolecules such as insulin via the deep lung.

New DPI technologies in development by Inhale Therapeutic Systems and Alkermes are enabling the delivery of macromolecules to the deep lung. Leading this

field is Inhale's insulin product, currently in the phase 3 trials with Pfizer. In the next years, it is expected that dry powder inhalation will become a broadly accepted and effective means of delivering a wide variety of therapeutics—antibiotics, analgesics, antibodies, hormones, proteins, and perhaps gene therapeutics. The potential of this technology continues to be explored.

ACKNOWLEDGMENT

IMMUNOASSAY

Stephen G. Schulman

G. J. P. J. Beernink

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Immunoanalytical methods that are based on the selective, reversible binding of small molecules (drugs) or macromolecules by biologically derived antibodies have revolutionized the field of biomedical analysis. Immunoassays have allowed the determination of very small amounts of analytes that were previously unassayable in biological matrices by other techniques. Since the original work on the analysis of insulin by Berson and Yalow (1), immunoassay methods have been developed for the determination of a wide variety of drugs, pesticides, hormones, and biological proteins. Immunoassays are relatively simple procedurally. This has led to the development of many "kit-type" immunoassay systems that are used routinely for home diagnostics.

Antibodies that are used as reagents in immunoassays are, in general, molecules of the immunoglobulin G (IgG) type. They are produced by white blood cells in response to foreign substances introduced in mammalian species. Millions of years of vertebrate evolution have developed immunoglobulins into exquisitely discriminating devices capable of recognizing subtle differences between molecules; for example, a mouse can generate millions of different immunoglobulin specificities. These immunoglobulins combine specifically with the substances (antigens) that elicited their formation. This then triggers processes by which the foreign antigens are cleared from the organism, which is the ultimate goal of the immune process (2).

These molecules are heterogeneous, bifunctional glycoproteins in which the variable amino acid sequence in the polypeptide component provides its biologic activity. This polypeptide component is made up of two heavy or H chains (50,000 Da) and two light or L chains (20,000 Da), held together by disulfide bonds. The two binding sites of the antibody molecule appear to reside on the NH₂ terminal ends of the polypeptide chains (3). Antibodies produced by injection of foreign antigens into a host animal are structurally heterogeneous and respond to different aspects of the same antigen with different binding strengths and specificities. If the antibody-

producing blood cell can be isolated in a pure cell culture, however, only one particular antibody structure will be produced (4). Antibodies harvested from pure cell cultures are referred to as monoclonal antibodies, are homogeneous and react with only one or a few closely related antigens. The antibody producing cells which can be grown in culture are produced by cell fusion techniques and provide superior antibodies for use in immunoassays because of their identical specificities and binding strengths. Antigens must have molecular weights in excess of 10⁴ Da in order to evoke antibody production. However, small molecules, such as drugs, can be bound to macromolecular carriers and some of the antibodies produced from these will respond to the drug (hapten).

All immunoassay procedures take advantage of the specific reactions between antibodies and antigens. They involve measurement, directly or indirectly, of the extent of binding between antibodies (reagents) and antigens (analytes). Labels are used in conjunction with the antigens or antibodies so that the concentrations of molecular species can be measured instrumentally. Labels are entities that impart some measurable signal, such as radioactivity, fluorescence, chemiluminescence, or electrochemical or enzyme activity to the antibody or antigen to which it is attached. The determination of the extent of antibody binding requires measurements of the amounts of labeled antigen or antibody in the complexed (bound) and in the free forms. This is generally expressed as the bound/free (b/f) concentration ratio, which is related to the concentration of analyte (5). The measured signal can be either directly or inversely proportional to the b/f ratio depending on the chemistry of the system used. There are two ways to determine the amount of antigen present: one using a limited amount of reagent (competitive assays), the other using an excess amount of reagent (noncompetitive assays).

The competitive assay uses a limited amount of antibody, which is insufficient to bind all of the antigen. The antigen competes with a fixed amount of labeled antigen for the limited number of antibody binding sites. From the proportion of bound (or free) labeled antigen, the concentration of unlabeled antigen can be determined.

The noncompetitive assay uses an excess of antibody. Different approaches to detect the bound antigen have been developed, the most common use an antibody, in excess, coupled to a solid phase. The bound antigen is then detected with a second antibody labeled in a way that aids detection (e.g., radioactive, fluorophore, etc.). The amount of antigen in the sample is then directly proportional to the amount of labeled antibody captured on the solid phase.

Both assays require differentiation of bound label from free label. This can be achieved by two methods: heterogeneous assay or homogeneous assay. Heterogeneous assay separates bound label from free label using a means of removing the antibody. Homogeneous assay compares the signal of the label when antigen is bound to antibody compared to when the antigen is free.

RADIOLABELED IMMUNOASSAYS

The earliest (1) immunoassays made use of radioactively labeled antigens or antibodies. These analytes are referred to as radiolabeled immunoassays. Antibody binding sites are extremely specific and to retain this specificity the best option would be to replace a nonradioactive isotope in the tracer molecule by its radioisotope (e.g., replace hydrogen by ^3H). However when the substitution is made in a part of the molecule away from the antibody binding site, the choice of radioisotope can be governed by other considerations, such as half-life, availability, high activity, and radiochemical purity.

The most common radioactive label is ^{125}I , which is bound to antibodies and antigens by a variety of techniques including chloramine-T, iodogen, or lactoperoxidase iodination. Iodination with ^{125}I is the preferred radiolabeling technique because the isotope is a γ -emitter, inexpensive, can be easily detected, has an appropriate half-life for most analytical purposes, and can be obtained in preparations with high specific activity. Problems occasionally associated with radioiodination include loss of immunoreactivity due to the size of the label or chemical alteration of reagents due to the high energy of decay (6). Use of beta-emitting isotopes (^{14}C and ^3H) may resolve these problems, but require more complicated scintillation counting for label measurement.

Labeled Antigen Radioimmunoassays

Labeled antigen radioimmunoassays involve competition between a labeled antigen and an unlabeled antigen

(analyte) for a limited number of antibody-combining sites as shown in the following reactions:

where Ag^* is labeled reagent antigen, Ag is analyte antigen, and Ab is antibody against Ag .

The Ag^* and Ab are analytical reagents with concentrations fixed so that when a sample containing Ag is added, competition between Ag and Ag^* for Ab binding sites occurs. Increasing concentrations of Ag result in a lesser degree of binding of Ag^* and the measurement of radioactivity of the binding or free fraction can be used to determine the amount of Ag present in a sample.

Determination of the distribution of Ag^* between the antibody-bound and free fractions, in radioimmunoassay procedures, requires a separation step which isolates Ag^* from Ag^*-Ab . Once separated, measurement of the radioactivity of the label in one or both the fractions provides a signal that is approximately exponentially related to the concentration of unlabeled antigen. The graphical relationship can have either a positive or a negative slope depending on whether the antibody-bound or free fraction is measured. The exact shape of the calibration curve however, is dependent on the antibody-binding equilibrium constant (7).

A variety of methods has been applied to the separation of bound and free Ag^* . These include precipitation, solid phase attachment, capillary electrophoresis, chromatography, and microfiltration. Originally, precipitation and solid-phase extraction were the most common types of separations techniques. However the ease of automation of capillary electrophoresis and flow-injection analysis (chromatography) makes these two techniques very interesting.

Precipitation

Precipitation techniques can be categorized into two general classes, nonspecific and specific. The nonspecific separations involve the addition of a salt or solvent that decreases the solubility of the antigen-antibody complex under conditions that do not affect the free-labeled antigen. After addition, the immune complexes can be precipitated by centrifugation and the radioactivity in either the supernatant solution or the precipitate can be measured. Examples of precipitation reagents used in immunoassays include alcohol, ammonium sulfate, polyethylene, and dioxane. Care must be taken to avoid coprecipitation of the unbound label.

Specific precipitation is a technique that has been devised to overcome some of the problems associated with nonspecific techniques. In this approach, a second

antibody (Ab'), specific to the analytical antibody is added in excess to cause precipitation of the primary antigen–antibody complex as shown below:

The method has been termed the double-antibody technique and can be used for a wide variety of analytes (8). The double antibody techniques generally require more time because the second antibody reaction can require days to reach equilibrium. The speed of precipitation clearly depends on the concentration of the second antibody. Polyethylene glycol has been used as a cosolvent to increase the precipitation rate.

Solid phase techniques

Many early immunoassays used solid phases to separate the labeled antigen from the complex by differential adsorption of the former. Examples of the solid phases used are dextran-coated charcoal, ion-exchange resins, and cellulose powder. Once the labeled antigen has been adsorbed, the bound, labeled antigen could be decanted to allow the measurement of the radioactivity of the bound and/or free-labeled materials separately. Because of problems with nonspecific adsorption and errors due to stripping of the labeled antigen from the solid, these types of separations have been largely replaced by those employing solid phases in which the reagent is covalently bound to the solid, as for example, in the solid phase attachment of a specific antibody (Ab^{SP}), which binds labeled and unlabeled antigen competitively as shown below:

The solid phase to which the antibody is bound can be either suspended in solution, on particles such as cellulose, agarose, or dextran beads or can be attached to the surface of a test tube or a microtiter plate. The stationary solid phases eliminate the centrifugation step that is necessary with the suspended beads although plastic solid phases have a limited capacity of binding proteins.

Capillary electrophoresis

This technique has proven to be a powerful separation technique for the separation of macromolecules, such as antibodies, for two reasons: the near flat plug flow profile and the small diffusion constant of the antibodies. These characteristics eliminate band broadening. With both superior separation power and high detection sensitivity, capillary electrophoresis (CE) can separate free Ab and Ag

from bound Ab and Ag rapidly and is suitable for immunoassays. CE can combine immunologic recognition with on-line quantitation, microscale analysis, and automatic instrumentation to offer unique advantages for immunoassays. In immunoassays CE can be coupled to all of the existing CE detection techniques from UV and laser induced fluorescence (LIF) to mass spectrometry (MS). CE coupled to LIF has been applied to the determination of a variety of compounds including therapeutic drugs, peptides, and antibodies (9).

Flow-injection analysis

This technique introduces a sample into a flow of reagents. The reaction proceeds during transport in a reactor, after which the product is measured downstream in a detector. By combining immunoassays with flow-injection analysis (FIA), the long incubation times usually associated with heterogeneous assays become irrelevant, since FIA exploits nonequilibrium conditions. The washing steps are performed automatically by the continuous flow of buffer. Besides the irrelevance of incubation times, another advantage over normal immunoassays is that the reactor can be used several times because regeneration by using a suitable agent (e.g., glycine HCl) is possible. Sequential injections can be used to deliver reagents, substrate (if necessary), and regeneration agents to the immunoreactor. Many different assays using electrochemical, fluorescent and chemiluminescent detection have been developed.

Labeled Antibody Radioimmunoassays (Immunoradiometric Assays)

The problem of binding proteins to solid phases can be avoided by employing a solid phase antigen (Ag^{SP}) and a labeled antibody (Ab^*) as shown in the following reactions:

Where the unlabeled antigen (the analyte) competes for antibody binding sites with the solid phase antigen. This approach may have some difficulties caused by the requirement for purification of the immunospecific antibody. Because monoclonal antibodies are produced as essentially immunospecifically pure populations, they are ideal for labeled antibody techniques.

Another approach that utilizes labeled antibodies is the so-called “sandwich technique” (10). In this method, the

analyte antigen is bound both by an antibody that is attached to a solid phase (Ab^{SP}) and a labeled antibody as follows:

The reaction is noncompetitive and thus, the concentration of unlabeled antigen has a direct relationship with the amount of label bound in the complex. The sandwich radioimmunoassays are both sensitive and convenient but are limited to analytes which are, at least, bivalent; i.e., antigens that can provide at least two sites for antibody attachment. Also, highly purified antibodies are required for the sandwich technique.

ENZYME IMMUNOASSAYS

Early work demonstrated the use of enzymes coupled to antibodies or antigens as reagents in immunoassay. Enzyme activity can be measured in a variety of ways, each with certain advantages, which makes a variety of enzymes good labeling substances. Most assay methods are based on spectroscopic properties derived from an enzymatically transformed substrate. These methods are colorimetry, fluorometry, luminometry, and electrometry.

The development of enzyme immunoassays was pioneered in 1972 by Engvall and Perlmann (11) and by Van Weemen and Schuurs (12) and is translated into a wide variety of enzyme-based systems used both in research and in routine analysis with sensitivities approaching those of radioimmunoassays. Enzyme immunoassays (EIAs) can be divided into two major classes, homogeneous and heterogeneous.

Homogeneous Enzyme Immunoassays

Homogeneous immunoassay (HOIA) does not require physical separation of the free and antibody-bound antigen because the measured physical signal derived from the antibody-bound, labeled material may be significantly different from that of the unbound entity. There may be an enhancement or an inhibition of enzyme activity upon binding of the antibody to the antigen. HOIA are simple to perform and automation can be carried out easily (13). Elimination of the separation step avoids a major source of imprecision in the assay. However selectivity may be compromised since interfering substances are not eliminated in the separation step.

HOIA using an enzyme labeled antigen

Rubenstein et al. (14) described a HOIA method for morphine using lysozyme as the enzyme label. The covalent enzyme labeled antigen (Ag^E) competes with sample antigen (Ag) for a limited concentration of antibody (Ab) to form a complex. The resultant complex exhibits very little enzyme activity because of either steric hindrance (14) or allosteric inhibition (15) caused by the bound antibody. In the presence of Ag there is competition for the Ab leaving more Ag^E uncomplexed and free to catalyze the conversion of substrate to product. Thus, the enzyme activity, which can be measured by either the appearance of product (P) or disappearance of substrate (S), is directly proportional to the amount of free antigen in the sample (16).

HOIAs based on this principle have been developed for a number of therapeutic agents and endogenous compounds using glucose-6-phosphate dehydrogenase (G-6PDH) under the name EMIT^R (Enzyme Mediated Immunoassay Technique). Enzyme activity is conveniently measured by absorption spectroscopy following the production of NADH from NAD which absorbs light strongly at 340 nm. The assay is rapid and sensitive to picomole levels (17).

HOIA using an antigen labeled enzyme modulator

This method is based on stability of an antigen labeled with an enzyme modulator (Ag^M) to modulate the activity of an indicator enzyme. The Ag^M competes with free antigen (Ag) for a limited amount of antibody (Ab). The Ag^M , on binding with Ab , is unable to modulate the activity of the indicator enzyme. As the concentration of analyte increases it competes successfully for binding sites on the antibody, leaving more Ag^M free to complex with indicator enzyme, thereby, modulating its activity (18, 19). A positive modulator will increase while a negative modulator will decrease enzyme activity. Thus, in the case of a positive modulator the enzyme activity will be directly proportional to the concentration of the analyte and

for a negative modulator the activity will be inversely proportional to the concentration of the analyte.

Based on this principle, practical assays for human serum thyroxine (20) and theophylline (21) have been developed and different distinct classes of modulators have been investigated.

HOIA using an antigen labeled with a fluorogenic enzyme substrate

This method was originally developed by Burd and Wong (22). The antigen is linked to a fluorogenic enzyme substrate (Ag^{FS}) to form a stable conjugate, which competes with the sample antigen (Ag) for a limited concentration of antibody (Ab). The antigen conjugated substrate is a fluorogenic substrate for the enzyme that reacts only when it is not bound to the Ab. Thus, at high concentrations of sample antigen, more of the Ag^{FS} would remain free to act as the substrate for the enzyme and more products would be formed. Thus, fluorescence intensity increases with increasing concentration of the sample antigen.

A derivative of umbelliferyl- β -galactoside serves as a fluorogenic substrate for *E. coli* β -galactosidase in this system (23) and solid-phase reagent strips based on this method have been developed (24).

HOIA using cloned enzyme donor immunoassay (CEDIA^{R})

This technique uses two different inactive enzyme fragments, a large fragment called enzyme acceptor (EA) and a very small fragment called enzyme donor (ED)

(25). Those fragments can associate to give an active enzyme.

In this technique, the antigen is labeled with enzyme donor (Ag^{ED}) capable of contributing to enzyme activation with enzyme acceptor (AD). When the labeled antigen binds to an antibody (Ab), the enzymatic activity is lost. The Ag^{ED} conjugate competes with sample antigen (Ag) for antibody complex formation. An increase in sample antigen concentration, therefore, leads to increased displacement of Ag^{ED} , leaving more free Ag^{ED} to associate with EA, resulting in more enzyme activation to form product (P). The enzyme activity is directly proportional to the amount of free sample antigen.

CEDIA s are available for the important relevant therapeutic drugs and most have picomolar detection limits.

Heterogeneous Enzyme Immunoassays

Heterogeneous immunoassays (HEIA) have at least one separation step which allows the differentiation of bound from free material. The enzyme-linked immunosorbent assay (ELISA), is a heterogeneous immunoassay which has been widely used. In this method, either antigen or antibody is immobilized on a solid phase. An essential difference from HOIA is that in HEIA the enzyme label is designed to retain its activity even after its reaction with the antibody. In comparison with RIA, non isotopic HEIA such as enzyme labeled assay has several important advantages, including better reagent shelf life, fewer health hazards and simpler equipment required. HEIA can be divided into the classes of competitive and noncompetitive assays.

Competitive assays

Enzyme-labeled antigen conjugate: In this assay, the enzyme labeled antigen (Ag^{E}) competes with sample antigen for a limited amount of antibody which has been immobilized on a solid-phase, for example, polystyrene (Ab^{SP}). After incubation, the unbound Ag^{E} is separated by washing with a detergent solution. The solid phase Ab^{SP} containing bound labeled and unlabeled antigen is incubated with a substrate (S) and the product

concentration is determined using a colorimeter or fluorimeter.

The enzyme activity or product concentration is inversely proportional to the concentration of sample antigen.

This method is very important for the measurement of low-molecular mass analytes such as steroids or melatonin or drugs such as cocaine (26). The most sensitive of these assays can detect <1 fmol analyte.

Enzyme-labeled antibody: This assay employs labeled antibody (Ab^{E}) and the antigen is attached to the solid phase (Ag^{SP}). The binding of Ag^{SP} to Ab^{E} is decreased by the addition of sample Ag.

The enzyme activity is inversely proportional to the concentration of sample Ag. Human IgG at the picomole level has been quantified in less than 1.5 h with this method (27). Estrone-3-glucuronide at the femtomole level has been quantified with this method.

Noncompetitive assays

Enzyme-labeled antigen: In this method, the sample is first incubated with a moderate excess of solid-phase immobilized antibody (Ab^{SP}). After washing, excess enzyme-labeled antigen (Ag^{E}) is allowed to bind to unreacted Ab^{SP} .

The concentration of P is inversely proportional to the concentration of standard or test antigen.

Enzyme-labeled antibody: The sample antigen (Ag) is incubated with a moderate excess of enzyme-labeled antibody (Ab^{E}). The mixture is then added to an excess of immobilized antigen (Ag^{SP}) to remove unreacted Ab^{E} .

The enzyme activity is inversely proportional to the concentration of sample and the procedure has been used to measure α -fetoprotein (28).

Sandwich or double antibody: This method is used with antigens having multiple antibody binding sites (epitopes). Immobilized unlabeled antibody (Ab^{SP}), in excess, is incubated with sample or antigen. After washing, the antibody-antigen complex is then incubated with an excess of enzyme-labeled antibody (Ab^{E}) which binds to one or more antigenic sites to form a sandwich type complex.

In this case, the concentration of enzyme product is directly proportional to the concentration of sample antigen.

Sandwich type assay is well suited for quantifying antigens with multiple antigenic determinants, such as antibodies, rheumatoid factors, polypeptide hormones, proteins, and hepatitis B surface antigens. The results obtained with sandwich type immunoassays are comparable to those obtained with those using radiolabels in term of precision, convenience and sensitivity. Highly sensitive thyroid-stimulating hormones assays are developed, as well as assays to measure estrogen and estradiol at attomole levels (29).

Avidin-Biotin Systems

An integral necessity of every enzyme immunoassay is the availability of enzyme-labeled antibody or antigen conjugates. The assays discussed in the first part of this article used chemical methods for forming these conjugates. An alternative approach has been widely employed that is based on the avidin-biotin reaction. Avidin is a protein of molecular weight about 60,000 that is found in egg white. It consists of 4 identical subunits. Each subunit binds biotin with an extremely high affinity. A dissociation constant of 10^{-15} corresponding to a dissociation half-life of about 160 days was reported. Hence, from a practical point of view, this binding can be regarded as almost irreversible in nature.

The rationale behind the use of the biotin-avidin system in immunochemistry is that avidin binds biotin

substituted structures. Peptides and proteins can be easily biotinylated via their amino groups by using activated biotin-*N*-hydroxysuccinimide.

Reagents for biotinylation of proteins and peptides are commercially available and allow the fast and efficient derivatization of antibodies and enzymes without the loss of enzyme or antibody activity. Several reagents are also available for the biotinylation of sulfhydryl groups aldehydes, nucleic acids and carbohydrates. Hence, in addition to proteins and peptides, a variety of antigens can be labeled with biotin.

Avidin can be coupled to enzymes by covalent binding techniques or by employing the so-called avidin–biotin complex (ABC). In the latter case, a complex between avidin and polybiotinylated enzyme is formed. The ratios of avidin to polybiotinylated enzymes are chosen in such a way that the resulting complex incorporates a number of enzyme molecules, but retains free biotin binding sites for the interaction with biotinylated antibody or antigen structures. A great selection of ABC complexes for a great variety of different enzymes is commercially available. The possibility of easily making biotinylated antibody or antigen structures and the availability of a variety of enzyme-labeled avidin derivatives or complexes facilitates the flexible design of enzyme immunoassays.

The most frequently used assay version uses a primary antibody which is immobilized to a solid support (e.g., the surface of a microtiter plate). In the first step, the antigen (analyte) is added to the wells. After the antigen is bound to the immobilized antibody, the wells are washed and a biotinylated second antibody is added to the tubes. The resulting sandwich between immobilized antibody; antigen and biotinylated antibody is incubated with the ABC complex. After washing, the antibody–antigen–biotinylated antibody–ABC complex is detected by addition of the enzyme substrate. The non competitive nature of this assay in conjunction with the extremely high amplification of the signal by the ABC complex results in an assay (in the femtomole range), that often exceeds the sensitivity of radioimmunoassays.

Competitive immunoassays based on the avidin–biotin approach have also been described. In this case, the antibody is immobilized on microtiter plates. Wells are incubated with a constant concentration of biotinylated antigen in the presence of different concentrations of standards or the sample. After washing, the ABC complex is added. The formed antibody–biotinylated antigen–ABC sandwich is then detected by the addition of enzyme substrate. The immobilized enzyme–activity is inversely proportional to the concentration of analyte in the sample, resulting in a typical sigmoidal calibration curve.

FLUORESCENCE IMMUNOASSAYS

Fluorescence immunoassay (FIA) entails the measurement of the photoexcited fluorescence from an antibody or antigen which participates in an immunochemical binding system, and whose spectral properties vary with the concentration of the analyte. Because few naturally occurring antigens and antibodies have the requisite fluorescent properties, they are usually substituted with fluorescent labels. Fluorescent labels are used in homogeneous and heterogeneous immunoassay systems and may be bound to competing (labeled and unlabeled) antigens; antibodies or solid phases or they may exist in solution as parts of enzyme substrates.

The fluorogenic molecules used to covalently label the antigens or the antibodies to be used in a fluorescence immunoassay are called fluorescent probes or labels. Fluorescent probes are small molecules whose fluorescent properties are altered subsequent to interactions with proteins or other macromolecules.

In quantitative immunoassay using fluorescent labels, there are several chemical and spectroscopic properties that the fluorochrome should possess. The labeled ligand should have a relatively high water solubility because immunoassays are usually carried out in the aqueous environment in which the antibodies are stable. The presence of certain functional groups on the fluorochrome will facilitate its conjugation to the ligand. Derivatives of the fluorochromes containing reactive groups such as acid chlorides, isothiocyanates and diazonium salts can be used for the conjugation of the label to the ligand. A major concern in labeling a ligand with a fluorescent probe is the possibility of altering the specificity of the ligand for its antibody. Consequently the site of the conjugation chosen should provide maximum exposure of functional groups necessary for antibody recognition. In addition, the stability and shelf life are also important considerations.

The spectral characteristics of greatest importance in the selection of a fluorochrome are the molar absorptivity at the selected wavelength of excitation, the quantum yield of fluorescence of the labeled species, the spectral regions of absorption and emission of radiation, and the Stokes' shift. Ideally, the fluorescent label should have an absorption spectrum with a high molar absorptivity in the visible region of the electromagnetic spectrum, well removed from the excitation spectra of proteins and other endogenous interferences normally present in biological fluids. The emission wavelength should also lie well into the visible region with Stokes' shift (displacement of the fluorescence maximum from the longest wavelength absorption maximum) of at least 50 nm. A high quantum

yield of fluorescence in the antibody-bound or free labeled ligand is also desirable.

The labels most commonly used are fluorescein isothiocyanate (FITC) and a number of reactive rhodamine dyes. Fluorescein isothiocyanate has a relatively high quantum yield and can be conjugated to drugs and other ligands under fairly mild conditions (30, 31).

Ligand labeling with fluorescent metal chelates has created a versatile class of fluorescent probes. The chelates of rare earth metals have unique emission characteristics in that, upon excitation of aromatic portions of the ligands of the lanthanide complex, the energy of excitation is efficiently transferred to the lanthanide ion. This causes $f-f$ transitions that produce very narrow almost line-like emission bands that permit all of the emitted light to be collected by the detector with narrow emission slits. In addition, the rare earth chelates possess large quantum yields in combination with very large Stokes' shifts. The excitation region of these chelates is fairly broad and these aspects of the lanthanide luminescence permit excellent sensitivity and selectivity by enabling the use of fairly wide bandwidths for excitation and narrow bandwidths for emission. With the proper combination of rare earth chelate and fluorimetric technique, very sensitive immunoassays can be developed that avoid a large number of interferences commonly encountered in the immunoassay process.

Homogeneous Fluorescence Immunoassay

Because of the extreme sensitivity of the quantum yield and spectral position of fluorescence to the microenvironment of the fluorophore, fluorescence immunoassay often lends itself well to homogeneous techniques. The elimination of the necessity of a step for the separation of bound and free ligand represents one of the major advantages of fluorescence immunoassay and provides the opportunity for simple, fast and reliable quantitation. The free and antibody-bound ligands reside in different microenvironments. In the aqueous environment, the free labeled antigen will experience strong polarizing forces as a result of interactions with water molecules. These forces will be exerted to different degrees in the ground and excited states of the labeled antigen because these electronic states have different dipole moments. Also, certain functional groups on the fluorophore may be free to rotate prior to and subsequent to the fluorescent transition in water. In the hydrophobic environment of an antibody binding site, the dielectric strength is low and rotation of functional groups on the fluorophore is severely restricted. The solvation and restricted rotational freedom of the antibody-bound labeled antigen usually cause this species

to fluoresce at shorter wavelengths than the free labeled antigen because the relative stabilization of the excited state of the latter by strong electrostatic and electromeric interactions is much greater than in the bound labeled antigen. Moreover, the weak solvation and restricted rotational freedom of the antibody-bound probe also cause the bound probe to fluoresce more intensely than the free probe because the bound probe is somewhat shielded from internal conversion which competes with fluorescence for deactivation of the excited state.

If the fluorescent emission spectrum of the bound labeled ligand is sufficiently displaced, enhanced or decreased in intensity (quenched) relative to that of the free labeled ligand, the resulting spectroscopic measurements can be used for quantitation without a separation step. Additionally, the techniques previously described in enzyme immunoassays, such as reactant-labeled immunoassay, can form the bases of fluorescent immunoassay. For example the fluorophore, from whose optical properties quantitation is derived, can be generated or consumed in an enzymatic reaction.

Two rather interesting variations on fluorescence immunoassay that do not require the fluorescence spectra of free and bound labeled materials to have different spectral positions have fairly recently become rather popular in clinical analysis. These are fluorescence polarization immunoassay and time-resolved fluorescence immunoassay.

Fluorescence polarization immunoassay (FPIA)

The physical principle underlying fluorescence polarization immunoassay involves the selective elimination of light waves whose electric vectors do not all lie in a single plane. This is accomplished by passing the exciting light through a polarizing filter. The resulting polarized radiation will selectively excite (photoselect) those molecules whose absorption transition moments have a significant component in the plane of the electrical vector of the exciting beam (32). As a result, molecules excited with polarized light will emit radiation that is polarized in the same direction as the exciting light, to a degree inversely related to the amount of Brownian rotation occurring during the interval between absorption and emission of light (33). This means that the photoselected molecules originally excited by polarized light and having fairly small volumes (i.e., free labeled antigen) will have random orientations with respect to the plane of polarization of the exciting light because they will rotate faster than they fluoresce. They therefore, will display very little polarized fluorescence. However, photoselected molecules having very large volumes such as the antibody

proteins and their complexes, will rotate at a rate comparable to or slower than the rate at which they fluoresce. Consequently, randomization of fluorescent transitions moments will not occur in these large molecules and substantial fluorescence polarization will be observed.

On binding of an antigen to an antibody there will be a reduction or a restriction in the rotational Brownian motion of the fluorescent label. This will cause considerable polarization of the fluorescence along or perpendicular to the optical axis of the excitation polarizer, depending upon whether the fluorescence transition moment of the molecule is oriented closer to 0 or 90° to the transition moment associated with the absorption band excited. Let us first consider the case where the transition moments for excitation and fluorescence are parallel (or nearly so).

If a second polarizing film (emission polarizer) is placed between the fluorescing sample and the photodetector of the fluorimeter, with its optical axis perpendicular to that of the polarizing film between the lamp and the sample, a much greater fraction of the highly polarized fluorescence from the antibody-labeled ligand will be filtered than would be of the unpolarized fluorescence from the same concentration of free labeled ligand excited under the same conditions. If the optical axes of both polarizers are parallel and the excitation and emission moments of the fluorophore are parallel, or nearly so, the emission polarizer will pass relatively more radiation from the bound labeled ligand than from the free labeled ligand, to the detector, because the unpolarized emission will be dispersed over all angles to the optical axis of the emission polarizer and some will therefore be filtered. Regardless of the orientation of the optical axis of the second polarizer with respect to the first, the fluorescence intensity registered by the detector should, ideally, be the same for unpolarized fluorescence (i.e., that of the free labeled ligand) while, in the case of parallel absorption and fluorescence transition moments, the intensity of the polarized fluorescence, from the bound labeled ligand, measured when the optical axes of the polarizers are parallel (F_{\parallel}) should be greater than when the optical axes of the polarizers are perpendicular (F_{\perp}). In the case of perpendicular absorption and fluorescence transition moments, for the free labeled ligand $F_{\parallel} = F_{\perp}$ (unpolarized fluorescence) and for the bound labeled ligand $F_{\perp} > F_{\parallel}$ (polarized fluorescence). We now define the degree of polarization as:

$$P = (F_{\parallel} - F_{\perp}) / (F_{\parallel} + F_{\perp}) \quad (1)$$

For a free labeled ligand $F_{\parallel} = F_{\perp}$ so that $P = 0$ at all excitation wavelengths. For a bound labeled ligand it is possible to have $+1/2 > P > -1/3$, depending upon the

wavelength of excitation. However, if a system is contrived which originally contains all antibody-bound, labeled ligand, upon addition of the unlabeled ligand the labeled drug will be displaced. The relative increase in unpolarized fluorescence and decrease in polarized fluorescence from the solution will cause a net decrease in P as calculated from its operational definition in Equation (1). If all the labeled ligand were ultimately displaced from the antibody complex, P would fall to zero. Depending on the extent of binding of the labeled ligand, the degree of polarization varies between some non zero value and zero. This permits the construction of a calibration curve of degree of fluorescence polarization versus concentration of unlabeled ligand and permits the execution of a homogeneous immunoassay.

The use of polarized fluorescence for the quantitation of several antigen-antibody reactions is widely used. Two assays of particular interest are those applied to the measurement of serum levels of gentamicin and phenytoin (30, 34, 35). The use of fluorescence polarization as a method for routine drug level determinations is limited by the light energy losses in the polarizing films and the background interferences that result in reduction of sensitivity.

Time-resolved fluoroimmunoassay

All of the fluorimetric techniques, so far considered, have been based on the measurement of the intensity of fluorescence produced under "steady state" conditions. "Steady-state" fluorimetry is derived from the excitation of the sample with a continuous temporal output of exciting radiation. The lamps and their power supplies used in conventional fluorimeters are sources of continuous radiation. After a short period of initial excitation of the sample, a steady state is established in which the rate of excitation of the analyte is equal to the sum of the rates of all processes deactivating the lowest excited singlet state (fluorescence, internal conversion, and intersystem crossing). When the steady state is established, the observed fluorescence intensity becomes time invariant and produces the temporally constant signal which is measured by the photodetector. With the development of modern electro-optics however, it has become possible to excite a potentially fluorescent sample with a thyratron pulsed flash lamp which emits its radiation in bursts of 2–10 ns duration with about 0.2 ms between pulses or with a pulsed laser whose pulses occur with durations upward of a few picoseconds. A fluorescent sample excited with such a pulsed source will not fluoresce continuously. Rather, its fluorescence intensity, excited by a single pulse will decay exponentially until the next pulse again excites the sample. The pulsed source then acts very

much as does a mechanical chopper in phosphorimetry. The fluorescence from the sample excited by the pulsed source can be represented, after detection, as a function of time on a fast sampling oscilloscope or on an x - y plotter used in conjunction with a multichannel pulse analyzer. The former approach is called pulsed-source fluorimetry and the latter, time-correlated single photon counting. In either case, fluorescence with decay times much longer than the lamp pulse characteristics can be treated in the same way that radioactive decay curves are analyzed. A semilogarithmic plot of fluorescence intensity against time will yield a straight line (or a series of intersecting lines if several fluorophores have comparable, but not identical decay times) whose slope is proportional to the decay time and whose vertical axis intercept can be compared with that of a standard solution of the fluorophore for quantitative analysis. If, however, the lamp pulse time and the decay-time of the fluorophore are comparable, the lamp characteristics must be subtracted from the observed signal to obtain the fluorophore's decay characteristics. This is usually accomplished by using a computer to solve a deconvolution integral representing the composite temporal characteristics of the lamp and the fluorophore output.

The pulsed-source (time-resolved) method, then effects spectroscopic separation of the emission of several fluorescing species by taking advantage of differences in their decay times rather than their fluorescence intensities. This means that several overlapping fluorescences, such as those of free and antibody-bound ligand can be quantified simultaneously. Lanthanide chelate-labeled antibodies, which have long lifetimes (in the $1 = \text{ms}$ to $1 = \mu\text{s}$ range) form the basis of a time-resolved FIA, for which instrumentation is commercially available.

Heterogeneous Assays

Most research and development of fluorescence immunoassays, to date, have been concentrated in the area of homogenous assay. Unfortunately, homogeneous assays may not always provide optimum analytical sensitivity. This may be due to the endogenous background fluorescence of proteinaceous materials, Rayleigh and Raman scatter caused by proteins or to the lack of environmental sensitivity of the emission from the fluorescent label. Notwithstanding the speed and simplicity of the homogenous assay procedures, it is occasionally desirable to circumvent these problems by physically separating the antibody-ligand complex from other species in the sample before fluorimetric quantitation.

The separation of the antibody-bound ligands from free ligands and other fluorescing species present in solution can be accomplished by various methods based on the

chemical, physical or immunological differences between the free ligand and the antibody-ligand complex and include gel permeation chromatography, chemical precipitation with inorganic salts or organic solvents and double antibody methods as well as the use of a solid phase support to which the antibody is either adsorbed or bonded covalently. In the latter method, the solid material may be paper discs, the walls of test tubes, glass or plastic beads, cross-linked dextrans or agaroses. Once the antibodies are immobilized on the solid support, the labeled and unlabeled ligands are introduced and allowed to compete for available binding sites on the antibody. The bound, labeled fraction is then separated from the free labeled ligand by washing. The labeled ligand complexed to the antibody can then be measured directly, without removal from the solid phase, by a fluorimeter with a front-surface fluorescence attachment (36).

CHEMILUMINESCENCE IMMUNOASSAYS

In all exergonic reactions energy is released. This energy is generally emitted as heat. In some reactions, however, this energy is released as light, a phenomenon known as chemiluminescence. During the course of chemiluminescence reactions, one or more of the resulting products is formed in an electronically excited state. Light is then emitted from the excited molecules by the process of fluorescence. Chemiluminescent reactions are almost invariably oxidation-reduction reactions. A number of compounds that show chemiluminescence of an intensity that is suitable for analytical detection systems or that are catalysts or reagents in chemiluminescent reactions have been investigated to be used in chemiluminescence immunoassays. Among these are synthetic organic compounds (e.g., phthalazinediones, acridinium esters), cofactors in bioluminescent reactions (NAD and ATP) and enzymes (peroxidase, oxidases, kinases, luciferases).

Covalent linking to either the antigen or antibody is carried out by chemical modification of the label (e.g., diazotisation or reaction with isothiocyanate, *N*-hydroxysuccinimide, hemisuccinate, imidoesters), by chemical modification of antigen or antibody (e.g., by reaction with hemisuccinate, glutaraldehyde), or by conjugation using bifunctional reagents (e.g., mixed anhydride carbodiimide, bis (N-hydroxy succinimides) or azidosuccinimides).

One of the most intensely chemiluminescent compounds is luminol (5-amino-2,3-dihydrophthalazine-1, 4-dione). If the amino group is linked to position 6 of the aromatic ring, the molecule is called isoluminol.

Isoluminol can be easily attached to antibodies or antigens via alkyl spacer groups. Aminobutylethylisoluminol (ABEI) has been shown to be very effective as a chemiluminescence labeling group, since the activity is generally not changed by coupling to low- or high-molecular-weight compounds. It can be easily coupled to activated carboxylic groups of immunologically relevant compounds using the mixed anhydride reaction (37). Proteins such as antibodies can be labeled sufficiently with ABEI through reaction of free amino groups of the proteins with an ABEI-isothiocyanate derivative (38).

The oxidative reactions of luminol and isoluminol derivatives at high pH result in the formation of 3-aminophthalate or 4-aminophthalate and nitrogen via an electronically excited state. The transition from the excited to the ground state induces the emission of light having a wavelength maximum of 425 nm. Quantitation is possible at picomolar or even attomolar levels of the aminophthalhydrazide.

In aprotic solvents, only oxygen and a base are necessary for the oxidation. In protic solvents a catalyst has to be present, in addition. As catalysts, enzymes such as horseradish peroxidase are frequently employed.

Acridinium esters are used also in immunological procedures. They have the advantage that no catalyst is necessary for the luminescence reaction. The solution has to be adjusted to a pH of 6–7 before the oxidant peroxide is added in order to ensure the highest activity.

Direct Chemiluminescence Immunoassays

The above reactions can be used in an immunological assay by coupling the chemiluminescent compound to an antigen or antibody; under the assumption that the immunological and chemiluminescent properties of the derived coupling product are not substantially changed. The approach to coupling chemiluminescent molecules to the required ligand obviously depends on the nature of the two species. When both species are small molecules, conventional synthetic organic chemistry can be used. A problem arises however when one or both molecules are more complex (e.g., proteins). Since the functionality of these molecules is determined by the chemical and physical environment, the range of chemistries that can be used is limited. As an example of direct chemiluminescence immunoassay, antibody might be immobilized onto a solid support and antigen allowed to bind to this antibody. After subsequent washing, a second chemiluminescent-labeled antibody that recognizes a different epitope of the antigen is added. After further washing, the chemiluminescent label is activated and the emitted light is quantified.

Since this assay is based on the sandwich principle, increasing amounts of analyte will produce increased light emission.

A chemiluminescent assay using competitive immunological techniques can be easily designed when chemiluminescent antigens are employed. In this case chemiluminescent antigen and sample compete for immobilized antibodies. Depending on the nature of the reaction antigen, bound and unbound label can also be separated by adsorption onto charcoal.

Indirect (Enzyme-Mediated) Chemiluminescence Immunoassays

An indirect chemiluminescence immunoassay is an assay, with another component than the primary chemiluminescent emitter coupled to the antigen or antibody. This can be a cofactor or a catalyst or even a molecule capable of converting a nonchemiluminescent precursor to a chemiluminescent or potentially chemiluminescent species. Most indirect assays are enzyme mediated.

One widely used enzyme mediated chemiluminescence immunoassay (39) uses the firefly enzyme luciferase that catalyzes the oxidation of D-Luciferin in the presence of ATP. D-luciferin, but not luciferin esters such as phosphates, is oxidized in the presence of the enzyme. An antigen or antibody-enzyme conjugate (e.g., alkaline phosphatase conjugate) is bound to a solid support by an antigen-antibody reaction. The immobilized enzyme enzymatically releases D-luciferin, which subsequently is quantified in a luciferase based lumino-metric assay, here described for the determination of alkaline phosphatase.

The chemiluminescent signals of luminol derivatives can be enhanced by the addition of firefly luciferin to the reaction mixture using hydrogen peroxide as oxidant and horseradish peroxidase as catalyst (40). This causes prolongation of the light production. Benzothiazoles, such as dehydroluciferin and 6-hydroxybenzothiazole derivatives also enhance the light emission by a factor of about 500 to 1000-fold and show a more constant light emission over time than luminol. A relatively constant emission of light over a period of 15 min has been observed for these derivatives (41). This constant and prolonged light emission pattern simplifies the analytical procedures as multiple reactions can be initiated outside of the luminometer without the necessity of initiating the chemiluminescence reaction in front of the photomultiplier.

Another chemiluminescent enzyme system is based on the use of stabilized dioxetane substrates. Dioxetanes are intermediates in many chemiluminescent reactions. It's possible to synthesize stabilized dioxetanes (phosphatase

and β -galactose moieties) that do not spontaneously react. When exposed to the right enzyme (alkaline phosphatase and β -galactosidase, respectively) the dioxetane will be destabilized and spontaneously undergo a chemiluminescence reaction (42).

ELECTROCHEMICAL IMMUNOASSAYS

Electrochemical immunoassays include a wide variety of devices based on the coupling of immunological reactions with electrochemical transduction. All of them involve the immobilization of an immunoreagent component on the surface of the electrode transducer. Electrochemical detection is based on the direct intrinsic redox behavior either of an analyte species or of some reporter molecule. For the detection no expensive equipment is needed, with the measurement of either a simple current or a voltage charge. Different electrochemical detection strategies are used, but amperometric detection is most widely used. Potentiometric and conductometric detection are applied in different assays as well.

For the detection different electrode supports and a great variety of immobilization procedures have been used. Gold electrodes, screen-printed electrodes and carbon materials (such as graphite and glassy carbon) have been frequently used. The sensing phase is constructed onto the surface of the electrode by means of covalent linkage, physical adsorption or membrane entrapping of the specific immunoreagent.

The major advantage of electrochemical immunoassays is the fact that it's based on the use of a nonoptical detection system, which makes it possible to detect signals in the presence of whole blood samples. There are three different ways in which electrochemistry is used in a detection system.

Direct monitoring of the antigen–antibody reaction

This is by far the simplest approach to electrochemical immunoassay, because there is no label needed. There are several methods demonstrated by analyzing simple solutions, however, considerable work will be necessary for detection when sensors are exposed to biological sample matrices.

Using electroactive compounds as labels

In order to be used as an immunoassay label, an electrochemically active compound has to possess suitable electrochemical properties. It has to be soluble in aqueous media and should be stable in solution over a wide pH range. To be detectable, it must allow highly selective

electrochemical detection or possess chemical properties to allow selective membranes to be used in the measurement electrode.

One of the advantages of an intrinsically electroactive label is that there is no need for substrate, cofactor or the special incubation steps for an enzyme label. However a consequence is the loss of enzyme signal amplification which increases the demands on detection sensitivity. Human serum albumin has been detected in a competitive heterogeneous assay using indium ions (43).

Using enzymes as amplification labels with the enzyme monitored by measurement of an electro-active product or substrate

The direct detection of electrochemical labels entails problems with sensitivity. For this reason the majority of electrochemical immunoassay development has focused on the measurement of enzyme labels by detection of electroactive products arising from enzyme catalyzed reactions. A wide variety of enzyme labels have been used for electrochemical immunoassays. These include glucose oxidase, glucose-6-phosphate dehydrogenase and alkaline phosphatase (44).

Glucose oxidase catalyses the conversion of glucose to gluconic acid with reduction of oxygen to hydrogen peroxide. In principle, either the consumption of oxygen or the liberation of hydrogen peroxide can be monitored to detect the activity of glucose oxidase. However due to the high background level of oxygen in biological fluids, hydrogen peroxide monitoring is more often used. Other glucose oxidase assays have been used (e.g., ferrocene and 1,4-benzoquinone), where oxygen is replaced by an alternative electron acceptor because of faster reaction rates, lower oxidation potential and the detection system is less sensitive to the levels of oxygen in the sample. A homogenous assay based on ferrocene was developed for digoxin (45).

Glucose-6-phosphate dehydrogenase catalyses the conversion of glucose-6-phosphate to 6-phosphogluconate while reducing NAD^+ to NADH. However the direct electrochemical measurement of NAD(P)H is rather difficult, owing to by a high overvoltage that is required for the electrode reaction and by electrode fouling. By using redox mediators (e.g. quinones, ferrocenes, and phenoxazine) these problems can be overcome. Theophylline, and phenytoin have been detected using glucose-6-hydrogenase.

Alkaline phosphatase is one of the most suitable enzymes for electrochemical immunoassays owing to its high turnover number and broad substrate specificity. Different substrates have been used, but 4-aminophenyl phosphate is most suitable, since the reaction product,

4-aminophenol is easily oxidized without fouling of the electrode surface. Thyroxine-binding globulin, cortisol, and prostatic acid phosphatase have been detected by using alkaline phosphatase.

LIPOSOME IMMUNOASSAYS

Liposomes are formed when phospholipid molecules spontaneously self-assemble in aqueous solution to produce spheres in which an aqueous cavity is enclosed by one or more phospholipid bilayer membranes. This cavity can be used to entrap a variety of materials. For immunoassays, a variety of detectable labels, called markers, have been encapsulated. The markers used range from inorganic salts [e.g., KCl, $K_4Fe(CN)_6$] for electrochemical detection, through widely used fluorescent markers (e.g. calcein, carboxyfluorescein, sulforhodamine B and chelates) to enzymes (e.g., alkaline phosphatase, horseradish peroxidase, and glucose-6-phosphate dehydrogenase). A wide range of detection methods and substrates is available for these enzymes. The amount of the encapsulated molecule is directly related to the amount of antigen. To achieve the lowest limit of detection the amount of encapsulated molecule (marker) should be as high as possible. Fluorescent markers are most commonly used because these markers can be measured easily and very sensitively. Besides these mostly small fluorescent molecules larger molecules, as enzymes and enzyme cofactors are also entrapped. The advantage of using larger molecules is that they tend to leak less through the liposome membrane. Most markers are water soluble, but lipophilic markers (e.g., perylene derivatives) can also be incorporated in liposomes (46). These markers are mainly incorporated in the membrane which eliminates leakage.

The amount of liposome-encapsulated marker has to be related to the amount of antigen, therefore the liposome has to be conjugated to the antigen. This can be done either directly or indirectly. With the direct approach the liposome is bound to the antigen. The indirect approach either uses an antibody or a secondary molecule bound to the liposome.

Homogeneous Liposome Immunoassays

Because of the special structural characteristics of liposomes it's possible to develop adapted schemes exploiting these characteristics. It's essential that the liposomes retain their structural integrity in the presence of lytic agents, which might be present in biological fluids.

However most liposome immunoassays use a natural lytic agent, the two most frequently used are complement (47) and mellitin (48).

When foreign cells enter the human body they are captured by antibodies, which attach themselves to the cell membrane surface. Complement binds to these antibodies in a specific order, after which the target cells are lysed. Because the liposome bilayer is structurally similar to the cell wall, complement can be used to completely lyse antibody-bound liposomes. Attention has to be paid to the fact that although complement is specific, some liposomes are susceptible to complement lysis, without being bound to an antibody. Most liposome immunoassays are homogeneous complement-based assays.

Mellitin is also able to lyse liposomes completely, although rather slowly, it is found in bee venom and its biological task is cell destruction. Cytolysin mediated assays use a conjugate of mellitin with the antigen. The conjugate is free and able to lyse the liposomes or bound to an antibody and unable to lyse the liposomes. The activity is thus reversed, proportional to the amount of antibody present in the sample. The disadvantage of mellitin-based assays is that the range of antigens is limited in size, because the presence of a large antigen will inhibit the activity of mellitin. Biotin and digoxin have been analyzed by a homogeneous liposome immunoassay using mellitin as lytic agent.

Homogeneous liposome immunoassays using lytic agents other than complement and mellitin have also been used. Phospholipase C catalyzes the dephosphorylation of phospholipids, which in turn destabilizes the liposome. The assay is based on the inhibition of the lytic activity by an antibody binding to an antigen conjugated to phospholipase C (49). Gentamicin is analyzed by this method.

Assays that use liposomes coated with murine monoclonal antibodies and magnetic particles coated with antimurine monoclonal antibodies, have been developed. Incubation of these two components results in destabilization of the liposome by binding to the magnetic particles. As a result the entrapped marker will be released (50).

Heterogeneous Liposome Immunoassays

Compared to homogeneous assays only a small number of heterogeneous assays have been developed. As all heterogeneous assays, a heterogeneous liposome immunoassay or a liposome immunosorbent assay always use one or more steps to separate the specifically bound liposomes from the free liposomes by washing. After washing lysis of the liposomes can be performed with a detergent which effectively and quickly lyse all liposomes,

such as Triton X-100. These assays can be regarded as modifications of enzyme-linked immunoassays.

We have presented in this article a brief overview of existing immunological assays. New drug developments will, in the future, require more versatile and sensitive assays. It can be said with certainty that immunological assays will retain their importance for achieving these goals.

INTRODUCTION

The term “hydrolysis” describes a chemical reaction in which a chemical bond is split (lysis) via the addition of water. This reaction is one of the most important routes of drug decomposition, as it occurs frequently in active ingredients and excipients of pharmaceutical dosage forms. A search of the scientific literature, performed with a popular electronic database and using the combination of keywords “hydrolysis” and “drugs,” yielded over 3300 articles from January 1989 to September 1999. A more selective analysis of a collection of stability data on 91 drugs (1) shows that 70 of these undergo hydrolytic degradation reactions. Of these, 61% can be classified as reactions of carboxylic acid derivatives, 4.3% of phosphoric acid derivatives, 20% of carbonyl derivatives, and 14.3% are nucleophilic displacements, often on the aliphatic carbon. These classes are discussed in the subsequent sections of this chapter.

HYDROLYTIC REACTIONS AND MECHANISMS

Carboxylic Acid Derivatives

Some drugs contain an acyl group, RCO^- in the compound RCOX , where X is called the leaving group. The most important types of acyl or carboxylic compounds, also called carboxylic acid derivatives are given in Table 1. The characteristic reaction of acyl compounds involves cleavage of the $\text{C}-\text{X}$ bond. The net result of the attack of a nucleophile Y^- on an acyl compound is cleavage of the $\text{C}-\text{X}$ bond and formation of the $\text{C}-\text{Y}$ bond; these reactions, shown in Eq. 1, are, therefore, called acyl transfers.

In a hydrolysis, H_2O (or OH^-) is the attacking nucleophile, and hydrolysis of a carboxylic acid derivative

is an acyl transfer to water, as in Eq. 2.

An important example of acyl transfer reactions is ester hydrolysis, where two sites of bond cleavage, both leading to the same product, are possible. The possibilities, shown in structure 1, are denoted acyl-oxygen fission (Ac) and alkyl-oxygen fission (Al).

Alkyl-oxygen fission constitutes a nucleophilic substitution on carbon, shown in Eq. 3.

Several experimental methods have been devised to establish the type of cleavage in ester hydrolysis; in nearly all cases, it is found to be acyl-oxygen cleavage via nucleophilic attack on the carboxyl group. Ester reaction mechanisms are often discussed in terms introduced by Ingold (2), who classified the type of bond fission (Ac or Al), the reaction molecularity (1 or 2), and the ionic form of the substrate (A for the conjugate acid $\text{RC}(\text{OH})\text{OR}^+$ and B for the conjugate base RCOOR). Ingold's classification is shown in Table 2.

For the bimolecular reaction with Ac cleavage, two reasonable mechanisms have been suggested. The first is a direct displacement analogous to the $\text{S}_{\text{N}}2$ mechanism of aliphatic nucleophilic substitution. This route is shown in Eq. 4; structure 2 is the transition state (\ddagger), although it is

Table 1 Carboxylic acid derivatives

Structure	Chemical class	Comments
$\begin{array}{c} \text{O} \\ \parallel \\ \text{RC}-\text{Cl} \end{array}$	Acid chloride

$\begin{array}{c} \text{O} \quad \text{O} \\ \parallel \quad \parallel \\ \text{RC}-\text{N}-\text{CR} \end{array}$	Imide	May also be cyclic and may be substituted
$\begin{array}{c} \text{RCH}-\text{CO} \\ \diagdown \quad \diagup \\ (\text{CH}_2)_n-\text{NH} \end{array}$	Lactam	May be substituted
$\begin{array}{c} \text{RCH}-\text{CO} \\ \diagdown \quad \diagup \\ (\text{CH}_2)_n-\text{O} \end{array}$	Lactone	
$\begin{array}{c} \text{O} \\ \parallel \\ \text{RC}-\text{OH} \end{array}$	Carboxylic acid	
$\begin{array}{c} \text{O} \\ \parallel \\ \text{RC}-\text{OR}' \end{array}$	Ester	Aliphatic or aromatic, depending on R'
$\begin{array}{c} \text{O} \\ \parallel \\ \text{RC}-\text{NH}_2 \end{array}$	Amide	Unsubstituted as shown or substituted by replacement of H
$\begin{array}{c} \text{O} \\ \parallel \\ \text{RC}-\text{SR}' \end{array}$	Thiol ester	

oversimplified because it does not incorporate electronic redistribution of the carbon–oxygen π double bond.

The second mechanism is the two-step addition–elimination pathway shown in Eq. 5; it invokes the

formation, by nucleophilic addition to the carboxyl group, of tetrahedral intermediate, **3**.

In 1951, Bender provided the first diagnostic test of mechanism for these reactions (3). The alkaline hydrolysis of several benzoate esters, a $\text{B}_{\text{Ac}}2$ reaction, was studied with

Table 2 Classification of ester hydrolysis reactions

Conjugate form	Type of fission	
	Acyl	Alkyl
Acid	A _{Ac} 1	A _{Al} 1 (S _N 1)
	A _{Ac} 2	A _{Al} 2 (unknown)
Base	B _{Ac} 1 (unknown)	B _{Al} 1 (S _N 1)
	B _{Ac} 2	B _{Al} 2 (S _N 2)

esters enriched in ^{18}O at the carbonyl oxygen. If the S_N2 mechanism in Eq. 6 is operative, no ^{18}O exchange with the solvent during hydrolysis would be expected, because the carbonyl oxygen does not engage in any reversible step. The tetrahedral intermediate mechanism, however, provides a route for ^{18}O exchange, concurrent with hydrolysis, by the symmetrical partitioning shown in Eq. 7.

When ethyl benzoate carbonyl- ^{18}O was subjected to alkaline hydrolysis, samples of ester isolated during the

progress of the reaction were found to contain less ^{18}O than the initial ester. This demonstration of concurrent oxygen exchange and hydrolysis is strong (though not definitive) evidence for the tetrahedral-intermediate mechanism. In other reactions, evidence of different kinds supports the tetrahedral-intermediate mechanism; for example, the intermediate has been detected spectroscopically in certain instances. In some reactions, it has been possible to identify a change in the rate-determining step as the pH is changed; this observation can be explained only by invoking a two-step reaction mechanism.

The two-step addition-elimination is taken here as a mechanistic description of the hydrolysis reaction. Alkaline ester hydrolysis is the example given in Eq. 8.

The differential rate equation for the intermediate (I) is given by Eq. 9.

$$\frac{d[\text{I}]}{dt} = k_1 [\text{OH}^-] [\text{RCOOR}] - (k_{-1} + k_2) [\text{I}] \quad (9)$$

Because the intermediate is consumed as rapidly as it is produced, its concentration is invariant over the time course of the reaction, and the steady state approximation can be applied to give Eq. 10.

$$[\text{I}] = \frac{k_1 [\text{RCOOR}] [\text{OH}^-]}{k_{-1} + k_2} \quad (10)$$

The rate of ester hydrolysis is $v = k_2 [\text{I}]$ or as in Eq. 11.

$$v = \frac{k_1 [\text{RCOOR}] [\text{OH}^-]}{k_{-1}/k_2 + 1} \quad (11)$$

The ratio k_{-1}/k_2 describes the "partitioning" of the tetrahedral intermediate between the reactant and the product states. The experimental rate equation is shown in Eq. 12.

$$v = k [\text{RCOOR}] [\text{OH}^-], \quad (12)$$

where k is the observed second-order rate constant. It follows that Eq. 13 holds that

$$k = \frac{k_1}{(k_{-1}/k_2) + 1} \quad (13)$$

If $k_2 \gg k_{-1}$, then $k \approx k_1$ and the first step is the rate-determining step (rds) of the reaction; if $k_2 \ll k_{-1}$, then $k \approx k_1 k_2 / k_{-1}$, and the second step (decomposition of the tetrahedral intermediate) is the rds. Eq. 13 provides a basis for the interpretation of structural effects on reactivity. Eq. 8 can be generalized to give Eq. 14

Eq. 13 applies to this kinetic scheme. Changes in the structures of R, X, and Y^- affect k through their separate effects on k_1 and k_{-1}/k_2 (4). The carboxyl group is polarized, as shown in structure 4.

Attack by the nucleophile Y^- , which may be OH^- or H_2O in hydrolyses, therefore, takes place at the electron-deficient carboxyl carbon and is aided by electron withdrawal at R and X. Such effects increase k_1 , and, hence, k . At the same time, these structural effects influence k_{-1}/k_2 . Increased electron withdrawal by R should make it more difficult for both X^- and Y^- to leave the tetrahedral intermediate, resulting in decreases in both k_{-1} and k_2 , with little change in the ratio k_{-1}/k_2 . Structural changes that increase the electron-withdrawing ability of X, however, tend to decrease k_{-1} and increase k_2 , thus decreasing k_{-1}/k_2 . The resultant effect on k depends upon the magnitude of k_{-1}/k_2 relative to unity, as in Eq. 13; in most cases, it appears k is dominated by k_1 .

The previous discussion can be used to interpret the hydrolytic behavior of a series of compounds that possess the same acyl group but varied leaving groups. For example, the order of hydrolytic reactivity for an amide, an ester, an anhydride, and an acid chloride is:

Such a series exhibits great variations in k_1 and k_{-1}/k_2 . The effect on k_1 in this series is a combination of inductive and resonance effects; the latter releases electrons from the leaving group to the acyl group, as indicated in structure 5.

These effects make k_1 smaller for amides than for esters, for example. At the same time k_{-1}/k_2 is affected by the ability of the leaving group (its "nucleofugality"). In the reverse of the k_2 step, that is, an attack by the nucleophile X^- , the more basic X^- , the more effective it is as a nucleophile. Hence, the more basic the leaving group X^- , the less effective it is as a leaving group, and the smaller is k_2 . The order of increasing basicity of the leaving groups in the above series is $\text{Cl}^- < \text{RCO}_2^- < \text{RO}^- < \text{NH}_2^-$, and, therefore, k_2 is smaller for the amide than for the ester and so on. The ratio k_{-1}/k_2 is highest for the amide, and k , the hydrolytic rate constant, is the smallest. Because the basicity of the leaving group can be measured by the pK_a of its conjugate acid, correlations of reactivity (expressed as $\log k$) with the pK_a of the leaving group (for a constant acyl group) are often successful. Thus, aromatic esters (leaving group a phenoxide ion) are more reactive than are aliphatic ester (leaving group an alkoxide ion.)

A very important example of ester hydrolysis of a pharmaceutical is that of the anion of aspirin, 6, given in Eq. 15

The marked instability of aspirin is due to two structural features: one, that it is an aromatic ester and, for reasons

previously discussed, it is, therefore, more labile than an aliphatic ester and two, the ortho relationship of the acetoxy group to the carboxylate. Owing to this proximity, aspirin is subject to intramolecular catalysis of the ester hydrolysis. The pK_a of aspirin is 3.6, and, therefore, it exists predominately in the anionic form above pH 5. This intramolecularly catalyzed reaction accounts for the hydrolytic instability of aspirin in neutral solutions. Additional pharmaceutical examples of hydrolysis of a lactone (a cyclic ester), an amide, and a lactam (a cyclic amide) are warfarin, acetaminophen, and the penicillins, respectively. Equations for these reactions are given in the first edition of this encyclopedia (5).

Phosphoric acid derivatives can be conveniently discussed with the carboxylic acid derivatives, owing to their similar reaction mechanisms. The structural class is extremely important biologically (6), but few pharmaceutical examples within it exist. For discussions of hydrolytic reactions of the phosphoric acid derivatives, the reader is referred to the first edition of this encyclopedia (5).

Derivatives of Carbonyl Compounds

The characteristic reaction of an acyl (carboxyl) compound $RCOX$ is cleavage of the $C-X$ bond. The reactions of carbonyl compounds, such as aldehydes $RCHO$ and ketones R_2CO , do not involve cleavage of the $C-R$ or $C-H$ bonds. Many drugs are derivatives of carbonyl compounds, though their parentage may not be obvious.

Carbonyl addition reactions take place with bond formation between the carbonyl carbon (which is electrophilic) and the nucleophilic portion of an adding species. The reaction of a reagent with a single dissociable proton can be described by Eq. 16.

This is a simple addition. If the reagent has two protons, a two-step addition-elimination occurs, as in Eq. 17.

Reaction (17) is a condensation reaction. The reverse of a condensation reaction is a hydrolysis of the $C-X$ bond, the process of interest here. This is shown in Eq. 18, where the product of the reaction is a hydrate.

Carbonyl compounds can form hemiacetals, **7**, which in the presence of acids can form acetals, as shown in Eq. 19, and they are subject to hydrolysis.

The hydrolysis of acetals (**8**, $R_2 = H$), ketals, and ortho esters (**8**, $R_2 = OR$) has been thoroughly investigated (7).

The overall reaction is given in Eq. 20:

The pathway, a unimolecular reaction of the conjugate acid (or A1 mechanism), is shown in Eqs. 21–24.

Much of the interest in acetal chemistry is related to carbohydrates, because polyhydroxyaldehydes exist predominantly as cyclic hemiacetals (8). Digoxin, for example, possesses acetal functions subject to hydrolysis.

The hydrolysis of imines is the reverse of the addition of amines to carbonyls, and the two-step scheme of Eq. 25 applies.

The kinetic behavior of this process depends upon the pH of the medium. In the alkaline region, the addition of

water is rate-determining, and the reaction probably involves attack of the hydroxide ion on the protonated amine (which is kinetically equivalent to attack by water on the neutral imine), as shown in Eq. 26.

At a somewhat lower pH, as the fraction of protonated imine increases (typical $\text{p}K_a$ values are 6–7) and the concentration of hydroxide decreases, the attack of water on the protonated imine becomes important, as shown in Eq. 27.

The rate becomes briefly pH independent when all of the imine is protonated, but with further decrease in pH, the rate-determining step shifts to loss of amine from the carbinolamine intermediate, as in Eq. 28.

The hydrolysis of nitrofurantoin, **9**, an example of the hydrolysis of an imine, is shown in Eq. 29.

Nucleophilic Substitution

Several classes of nucleophilic substitution reactions can be distinguished (in addition to similar processes, such as acyl transfer to a nucleophile): substitution on aliphatic carbons, on aromatic carbons, and on elements other than carbon, such as metals in metal-ligand coordination complexes. Of these, substitution on aliphatic carbon is most frequently encountered.

The reaction is of the type shown in Eq. 30

where the nucleophile Y^- may be anionic or neutral. In hydrolysis reactions, the nucleophile is H_2O or OH^- ; the hydrolysis of an alkyl halide, given in Eq. 31 is typical:

In aliphatic nucleophilic substitutions two mechanistic routes have been clearly identified; one is the two-step process shown in Eqs. 32, 33.

The first step, which is rate-determining, is an ionization to a carbocation intermediate that reacts with the nucleophile in the second step. Because the transition state for the rds includes $R-X$ but not Y^- , the reaction is unimolecular and is labeled S_N1 (substitution nucleophilic

unimolecular). First-order kinetics are observed, with the rate being independent of the nucleophilic identity and concentration.

The second mechanism is a one-step direct displacement reaction, shown in Eq. 34.

This bimolecular process is called the S_N2 mechanism. It yields second-order kinetics, unless the nucleophile is the solvent, in which case apparent first-order kinetics are seen. The species in brackets is the transition state.

The S_N reactions have been very carefully studied (9, 10). The S_N1 mechanism is favored by structural features that lead to stabilization of the carbocation, and, therefore, tertiary aliphatic substrates tend to react via the S_N1 route. Primary substrates react by the S_N2 mechanism. Secondary substrates may react by the S_N1 or S_N2 mechanism, depending the details of the reaction; alternatively, secondary substrates may proceed by a "borderline" mechanism having some features of both S_N1 and S_N2 . In solvolyses, the distinguishing characteristic of the S_N2 route is the covalent participation in the rds. The extent of such participation, which is absent in a pure S_N1 reaction, can be estimated by studying solvent effects (11) or the pressure effects (12) on reaction rates.

A pharmaceutical example of a nucleophilic substitution reaction is thiamine hydrochloride, **10**, which is cleaved, as shown in Eq. 35. The cationic moiety can support the electron transfer and is a good leaving group.

HYDROLYTIC KINETIC PHENOMENA

In the experimental study and interpretation of hydrolytic reaction rates, many kinetic effects provide opportunities

for probing the detailed nature of the reaction or have significant practical consequences on drug stability. The topics of temperature dependence, catalysis and solvent effects, were discussed in the first edition of this encyclopedia (5).

Hydrogels

María Dolores Blanco

Rosa Olmo

José María Teijón

Universidad Complutense de Madrid, Madrid, Spain

INTRODUCTION

Hydrogels are three-dimensional and hydrophilic polymer networks capable of swelling in water or biological fluids and retaining a large amount of fluids in the swollen state.^[1] The water content in the equilibrium of swelling affects different properties of the hydrogels: permeability, mechanical properties, surface properties, and biocompatibility. The utility of hydrogels as biomaterials lies in the similarity of their physical properties with those of living tissues. This resemblance is based on their water content, soft and rubbery consistency, and low interfacial tension with water or biological fluids.^[2]

Hydrogels can be prepared from a wide variety of materials, of natural origin, obtained from plants and animals, as well as from materials prepared by the modification of the aforementioned natural structures and from synthetic polymeric materials. Among the natural polymers, proteins such as collagen,^[3] and polysaccharides such as chitosan^[4] or hyaluronic acid^[5] are used. Regarding synthetic polymers, due to the singular properties that characterize them, as a consequence of their vast structural versatility, they are the materials that have experienced a greater growth and development in terms of their practical applications.^[6]

Hydrogels, which in a dehydrated state have a crystalline aspect and are called xerogels, apart from their immediate definition of being gels containing water, are polymers or copolymers with particular characteristics: They are hydrophilic and insoluble in water, and they swell in its presence (or in the presence of any aqueous fluid), increasing in volume and becoming soft and elastic, but keeping their shape, until reaching a physical–chemical balance. These characteristics are a consequence of diverse factors:

- Their hydrophilic nature is due to the presence of polar groups, such as $-\text{OH}$, $-\text{COOH}$, $-\text{CONH}_2$, $-\text{HSO}_3$ along the polymer chains.
- Their insolubility in water is due to the existence of a three-dimensional cross-linked network in their

structure. This cross-linking can be due to weak cohesive forces (forces such as van der Waals and hydrogen bridges) and due to covalent or ionic bonds.

- Their elastic consistency is determined by the hydrophilic monomer used and the low density of the cross-linking of the polymer.
- The conservation of the shape is a result of the balance between the osmotic forces originated by the water upon entering the polymer and the cohesive forces exerted by the polymeric chains that resist that expansion.^[7]

SYNTHESIS

Hydrogels, based on synthetic monomers, are synthesized through condensation polymerization or through free-radical polymerization. In terms of condensation polymerization,^[8] it is characteristic of compounds that contain reactive functional groups and it is produced between pairs of these functional groups, with the consequent release of small molecules, such as H_2O , NH_3 , or HCl . A clear example is the synthesis of poly(ethylene glycol) (PEG), a polymer soluble in water with numerous biomedical applications^[9] such as wound dressings and drug-delivery systems. Its molecular weight is below 20,000; polymers with higher molecular weights are called poly(ethylene oxide) (PEO). Poly(ethylene glycol) hydrogels are often prepared by radiation cross-linking of high molecular weight PEO^[10] or by chemical cross-linking by reaction of the hydroxyl groups on the ends of PEG. Poly(ethylene glycol) star polymer hydrogels have also been prepared by using γ -irradiation.^[11,12]

Another form of polymeric synthesis is by free-radical polymerization.^[13] These types of polymers are macromolecules formed by the incorporation of unsaturated monomer molecules, in other words, with a double bond, to the active center of a chain in growth. In most cases, these macromolecules are vinyl polymers. In Fig. 1, the chemical structure of some monomers used in the synthesis of hydrogels is shown.

Fig. 1 Chemical structures of some monomers used in the synthesis of hydrogels.

In the formation of addition polymers, a chain reaction is produced with three well-differentiated stages: (a) initiation, (b) propagation, and (c) termination. The beginning of the polymerization requires an activation of the monomers, whether it is thermal, photochemical, by free radicals, or ionic, which allows the binding of the activated monomer in the propagation stage; this way, lineal or branched polymeric chains are produced, depending on the chemical characteristics of the monomer used.

Regarding the initiation process of polymerization, it can be started by γ -radiation. It is a method that has been used for the synthesis of hydrogels of PEO^[12] as well as hydrogels based on vinyl monomers;^[14] in this latter case, azo-compounds such as 2,2-azo-isobutyronitrile (AIBN)^[15] or 2,2'-azobis(2-amidine-propane) dihydrochloride or V-50,^[16] and aqueous salt solutions such as aqueous ammonium peroxodisulfate^[17] are also used. Among the monomers most used in the preparation of hydrogels through free-radical polymerization are 2-hydroxyethyl methacrylate (HEMA)^[18] and *N*-vinyl-2-pyrrolidone (VP).^[19]

On many occasions, the hydrogels are made up of more than one monomer, in most cases by two types of different monomers, in this case being copolymers.^[8] The chemical structure of the copolymers depends on the concentration of the different monomers in the feed mixture and on the reactivity of the functional groups

that participate in the polymerization. In general, the copolymerization allows the mechanical properties and the swelling of the hydrogels to be modified. So, the copolymerization of HEMA with VP generates hydrogels with a higher water content in the swelling equilibrium than those of poly(2-hydroxyethyl methacrylate) PHEMA and whose mechanical properties worsen when the percentage of VP in the copolymer is increased.^[20] However, the copolymers of HEMA and methyl methacrylate (MMA), a monomer less hydrophilic than VP, are characterized by water content in the swelling equilibrium less than PHEMA hydrogels.^[21]

In the synthesis of a large number of hydrogels, cross-linking agents are used, which interconnect the lineal polymeric chains establishing a three-dimensional network of strong chemical bonds among them.^[18,19] It is necessary that the polymer has certain groups in its structure that can be used as anchor points in order to form the network. The cross-linking agent, whose choice depends on the selected monomers, must have at least two reactive groups in its structure, in order to be able to cross-link different polymeric chains, normally tetrafunctional and hexafunctional compounds, such as ethylene glycol dimethacrylate (EGDMA)^[22] and 1,1,1-trimethylolpropane trimethacrylate (TPT),^[23] although other cross-linking agents have also been used such as ethylenediaminetetraacetic dianhydride (EDTAD)^[24] and pentaerythritol triacrylate

Fig. 2 Chemical structures of some cross-linking agents used in the synthesis of hydrogels.

(PETA)^[25] (Fig. 2). The cross-linked polymers exhibit considerable differences in their properties depending on the degree of cross-linking and the preparation method. In general, the degree of cross-linking determines the degree of swelling, the pore size, the total surface area, and the mechanical resistance of the polymer.

The large deformation capacity of the elastomeric materials is due to the flexible nature of the polymeric chains that form them. This molecular flexibility (microscopic) allows its large macroscopic deformation capacity. If the chains that make up the elastomeric material are connected among themselves through covalent links, which connect them to each other, then the solid becomes a three-dimensional molecular network, the deformation of the polymeric matrix is only temporary

(while the application of deforming force lasts), and the recovery is reversible. These bonds or cross-links give continuance to the material, preventing the sliding of some chains with respect to others. The elastic properties of the material depend on the proportion of cross-links that are introduced in order to form the three-dimensional network (Fig. 3).

The *cross-linking density* is the number of points of cross-links present per unit volume of material. If the cross-linking density is low, the network will be very open and therefore, the chain sections that join two consecutive cross-links are long and their flexibility is hardly limited, causing the material to exhibit elastic behavior. If the cross-linking density is high, the network will be closely woven. In this case, the chain sections between cross-links

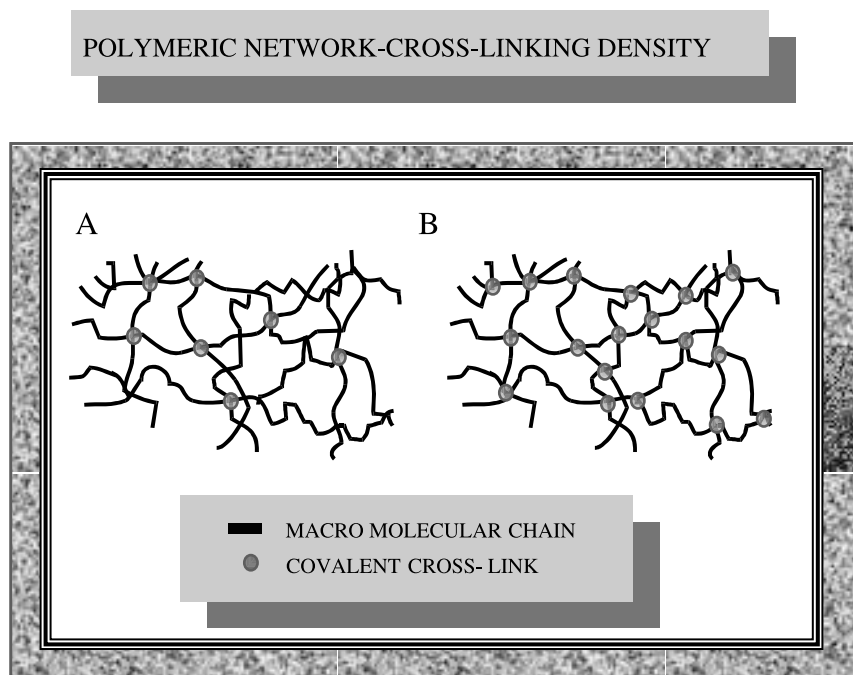

Fig. 3 Cross-linking density of a polymeric network: (A) low cross-linking density; (B) high cross-linking density.

are short and the chains are anchored by many points, causing the material to lose flexibility, and making it more rigid or stiffer.

However, the preparation of nonbond cross-linked polymer hydrogels of VP by copolymerization with the cross-linking agent cyclic octaethylene glycol fumarate, a 29-membered ring, having a polymerizable double bond has also been described. Treading of polymer chains into the macrocyclic rings is the cause for the cross-linking.^[26]

Regardless of the polymerization reaction that leads to the synthesis of a hydrogel, and that is basically conditioned by the type of monomer or monomers that make it up, there are several types of polymerization processes for the preparation of hydrogels: bulk polymerization, suspension polymerization, and emulsion polymerization. In the bulk polymerization, the system is made up of the monomers, the cross-linking agent, if a cross-linked gel is desired, and the initiator of the reaction, which are situated in a recipient, where the polymerization reaction is unleashed; this technique allows one to obtain hydrogels with a wide variety of morphologies in terms of the mold used for the synthesis, the most common being the preparation of cylinders^[15,16] and films.^[27] Some variants of this type of polymerization processes allow one to obtain macroporous

hydrogels.^[28] Macroporosity can be introduced into hydrophilic copolymer membranes by means of porosity technology; with this approach, monomers are copolymerized around a crystalline matrix, which is either dispersed or leached from the membrane after polymerization. The preparation of macroporous membranes by the freeze–thaw method requires the presence of a chemically inert material, which can form a crystalline structure around which the monomers can be polymerized; in the case of hydrophilic monomers, aqueous systems can be used, where the ice crystals constitute the crystalline matrices. Applying these technologies, Professor Tighe's group has prepared macroporous membranes of poly(HEMA) or poly(acrylic acid).^[28] Other researchers have prepared porous networks of poly(HEMA) using a thermally initiated free-radical solution polymerization.^[29]

In suspension polymerization, the drops of monomer, containing the initiator, are dispersed in a concentrated aqueous saline solution, which produces hydrogel beads. Applying this technique, Professor Ping I. Lee^[30] has synthesized PHEMA hydrogels. Hydrogels can also be prepared through emulsion polymerization,^[1,8] this way, emulsification methods can be used to obtain spherically shaped hydrogels from cross-linked polymers or copolymers.^[31]

PROPERTIES

There is a direct relationship between the properties of a hydrogel and its structure, in such a way that both characteristics cannot be considered in an isolated way because its polymeric composition and the synthesis method decisively influence the structure of the polymeric matrix as well as the final properties that the gel will have (Fig. 4). Therefore, when the properties of the hydrogels are presented, reference must be made to the structural parameters that condition them.

Swelling

Hydrogels are characterized, first by their capacity to absorb water or aqueous solutions. The water content in the swelling equilibrium of a hydrogel is affected, fundamentally, by the nature of the monomer or monomers that make it up, by the type and density of the cross-link, and by other factors such as temperature, ionic strength, and pH of the hydration medium.

The amount of the aqueous medium incorporated in a hydrogel is determined, generally, gravimetrically and can be expressed in several ways. The fractional hydration

$(W)^{[14]}$ can be obtained as follows:

$$W = (w_1 - w_0)/w_1$$

where w_1 and w_0 are the weights of swollen and dry gels, respectively.

The swelling ratio $(r)^{[16]}$ is expressed as:

$$r = (w_1 - w_0)/w_0$$

At a particular temperature, the volume fraction of polymer (ϕ_2) within a hydrogel at swelling equilibrium is given by:

$$\phi_2 = (D_0/D)^3$$

in which D_0 and D are the diameters of dry and swollen equilibrium discs, respectively, which can be determined using a micrometer or photographically.^[32]

Hydrogels formed from hydrophilic monomers contain larger percentages of water. So, for example, the content of water in the equilibrium of HEMA and VP copolymers increases when the content of VP in the gel is increased, obtaining percentages of fractional hydration of 38.3 wt% for hydrogels with a 25 wt% of VP in the feed mixture of polymerization and of 59.3 wt% for

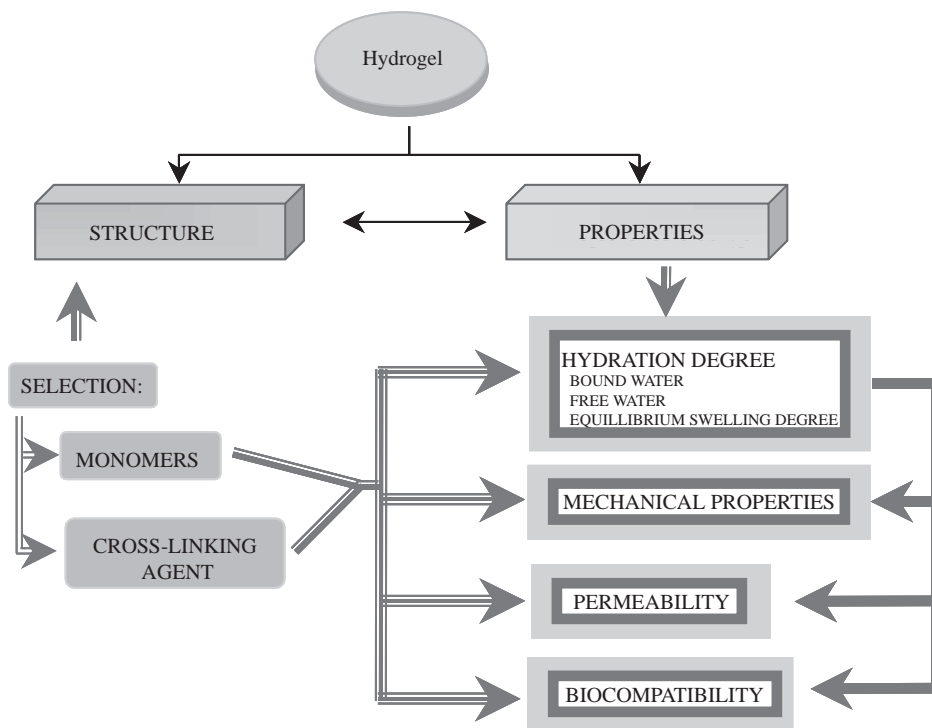

Fig. 4 Relationship between structure and properties of hydrogels. The selection of monomers and cross-linking agent determines hydrogel properties. On the other hand, a hydrogel with specific properties must be synthesized using specific monomers and cross-linking agent.

those that contain 50 wt% of VP, both cross-linked with 5 wt% of EGDMA.^[33]

Another variable that directly influences the capacity of the water absorption of hydrogels is the degree of their cross-linking. The increase in the content of cross-linking agent decreases the percentage of fractional swelling. So, for example, for PHEMA hydrogels, these values vary from 36 wt% to 29 wt% when the amount of the cross-linking agent (EGDMA) is increased from 0.5 wt% to 5 wt%.^[22] This same effect has been described for numerous hydrogels, for example, copolymers of HEMA and acrylamide (A) cross-linked with EGDMA,^[34] and copolymers of *N*-isopropylacrylamide (NIPA) and acrylic acid (AA) cross-linked with *N,N'*-methylene bisacrylamide (BIS) or with glyoxal bis(diallyl acetal) (GLY).^[35]

Likewise, the type of cross-linking agent also affects the water content in swelling equilibrium, so, for example, PHEMA hydrogels cross-linked with TPT (1 wt% of TPT) reach percentages of fractional swelling which are lower ($W = 27\text{--}23$ wt%) than those cross-linked with EGDMA, in the same conditions of synthesis.^[23] Also, copolymers of NIPA and AA experience greater swelling when they are cross-linked with GLY than with BIS.^[35]

There are hydrogels whose swelling is conditioned by the temperature and by the pH of the medium. Poly(*N*-isopropylacrylamide) (PNIPA) and its copolymers have been extensively studied in the development of thermoresponsive hydrogels. Cross-linked PNIPA exhibits a volume phase transition temperature (VPTT), at around 32°C in aqueous media. At temperatures below its VPTT, the cross-linked PNIPA matrix is superabsorbent and swells to form a hydrogel. On increasing the temperature above the VPTT, the hydrogel undergoes a rapid shrinkage. The thermosensitivity of the hydrogel is due to the hydrophilic–hydrophobic balance of its constituent polymer chains and is directly related to the lower critical solution temperature (LCST) phenomenon that is exhibited by linear PNIPA in aqueous solution.^[36] Furthermore, diverse copolymeric hydrogels of PNIPA have been synthesized, which are temperature sensitive.^[37,38] In addition, temperature-sensitive hydrophilic gel microcapsules of poly(*L*-lysineisopropylamide-terephthalic acid), containing water, have been obtained.^[39] The microcapsule changes its size between 33 and 35°C. Below 33°C the microcapsules are fully spherical while they are aggregated above 35°C; this thermosensitive morphological change is reversible. Another type of temperature-sensitive hydrogels has been prepared by the group of Yoshida and Carenza, which has synthesized poly(acryloyl-*L*-proline methyl ester)-based hydrogels cross-linked with TPT,^[40,41] which swell between 74% and 63%

(swollen hydrogel volume/dry hydrogel volume, %) at 4°C, and they shrink at 37°C.

The pH sensitivity of the hydrogels is due to the presence of weakly acidic and/or basic functional groups on the backbone. Their water uptake properties are provided by the ionization of the functional groups, which depends on the pH and on the ionic strength of the external medium. The Falamarzian group has synthesized diverse hydrophobic/polyelectrolyte copolymer hydrogels. They have reported that poly(methyl methacrylate/dimethylaminoethyl methacrylate) [MMA/DMA] cross-linked with divinylbenzene (DVB) hydrogels are polycationic pH-sensitive hydrogels, which are quite hydrated in acidic pHs while glassy in alkaline and neutral pHs.^[42,43] Also, chemically derived cross-linked polyacrylamide-grafted guar gum microgels possessing weakly anionic groups have been developed;^[31] due to the presence of ionizable carboxylic functional groups, these microgels are sensitive to pH and ionic strength of the external media. The rate of solvent diffusion increases considerably at higher pH, i.e., above the pK_a ($pK_a = 4.6$) of the anionic microgels. At higher pH, above the pK_a , the $-\text{COOH}$ groups may dissociate, thereby increasing the osmotic pressure inside the microgels resulting in a higher swelling. The electrostatic repulsion might cause the cross-linked network to swell, thereby allowing water molecules to enter into the matrix. Another type of pH-sensitive hydrogel is made up of copolymers of *N*-acryloyl-*N'*-methyl piperazine and MMA cross-linked with EGDMA.^[44] The high swelling observed at low pH ($\text{pH} = 2.6$) is due to the protonation of the tertiary amine group of the piperazine unit, which causes electrostatic repulsion thus leading to increased swelling. The swelling of the gel goes down in a solution of pH 7. Likewise, the hydrogels synthesized by cross-linking chitosan and polyvinyl pyrrolidone (PVP) blends with glutaraldehyde to form a semi-interpenetrating polymer network are pH sensitive;^[45] an acidic environment ($\text{pH} 1$ and 2) has a pronounced effect on the swelling profiles of hydrogels compared with neutral or alkaline media. Increased swelling of hydrogels, under acidic conditions, is due to the protonation of a primary amino group on chitosan.

Mechanical Properties

The mechanical behavior of the hydrogels can be described by the theories of rubber elasticity and viscoelasticity,^[46] which are based on time-independent and time-dependent recovery of the chain orientation and structure, respectively. Mechanical properties due to rubber elastic behavior of hydrogels can be determined

by tensile measurements, while the viscoelastic behavior can be determined through dynamic mechanical analysis.

The Huglin's group has determined the mechanical properties of diverse hydrogels through compression–strain measurements.^[32,35,47,48] Young's moduli of elasticity (E) can be obtained as the slopes in plots of stress (τ) vs. strain ($\lambda - 1$), where τ is the applied force per unit area of hydrogel and λ is the ratio of deformed length to undeformed length of hydrogel. These plots are linear over the range of strain covered.

The compression moduli (G) are obtained as the slope of τ vs. $(\lambda - \lambda^{-2})$ plot, at low strains: $\tau = G(\lambda - \lambda^{-2})$. Once the compression modulus is known, the effective cross-linked density (ν_e) can be determined from the following equation:

$$G = RT \nu_e \phi_2^{-1/3}$$

The effective cross-linked density is an experimental quantity, unlike the theoretical cross-linking density (ν_l), which is given by

$$\nu_l = Cf/2$$

where C (mol dm^{-3}) is the concentration of added cross-linking agent and f is its functionality.

Starting from the values of ν_e , the molar mass between cross-links (M_c) can be calculated:

$$M_c = \rho / \nu_e$$

where ρ is the density of the hydrogel, which can be obtained from the mass and the volume. The molar mass between cross-links can also be determined through the Peppas–Merrill relationship.^[49]

Likewise, starting from the values of ν_e , the polymer–water interaction parameter (χ) can be calculated using the following expression:

$$\ln(1 - \phi_2) + \phi_2 + \chi \phi_2^2 + \nu_e V_1 (\phi_2^{1/3} - 2\phi_2 f^{-1}) = 0$$

where V_1 is the molar volume of water ($\text{dm}^3 \text{mol}^{-1}$) at a specific temperature.

The mechanical properties of the hydrogels depend, fundamentally, on their composition and structure, and on many occasions they are weak, for which many of these materials cannot be used in load-bearing applications such as the replacement of damaged tissues. Although the quantity of water absorbed in the polymeric matrix of a hydrogel plays a very important role in its diffusion and permeability properties as well as its biocompatibility, it can negatively affect its mechanical properties in many cases. Furthermore, the state of the water in the hydrogel also affects its mechanical properties, because the increase

in the proportion of freezing water in the gel causes a worsening in its mechanical resistance, since that water is going to act as a plasticizer, decreasing the glass transition temperature of the system.^[21] The strategies to improve the mechanical properties of the hydrogels are, mainly, the cross-linking and the copolymerization with hydrophobic monomers.

The highly hydrophilic hydrogels, such as those consisting of PVP cross-linked with EGDMA (0.5 wt%–5 wt%),^[47] characterized by small values of the interaction parameter χ ($\chi = 0.49$ – 0.57), present small Young's modulus (0.019 MPa–0.504 MPa) that improve when the percentage of the cross-linking agent is increased. The copolymerization of VP with a hydrophobic monomer such as *n*-butyl acrylate (BA)^[48] notably improves the mechanical properties of hydrogels, whose compression modulus (G) increases when the amount of BA in the hydrogel is increased, from 0.046 MPa for hydrogels with 2 wt% of BA to 0.256 MPa for those with 60 wt% of BA, all of them cross-linked with 1 wt% of TPT, which corresponds to a decrease in their elasticity ($E = 0.148$ MPa– 0.0829 MPa). Also in these hydrogels, the increase in the cross-linking agent decreases elasticity, increasing the compression modulus ($G = 0.439$ MPa for hydrogels with 60 wt% BA and 2.5 wt% TPT), which is correlated with a more effective cross-linking density ($\nu_e = 0.115 \text{ mol dm}^{-3}$ – $0.195 \text{ mol dm}^{-3}$ for hydrogels with 60 wt% BA and 1 wt%–2.5 wt% TPT, respectively) and therefore will lower the values of molar mass between cross-links ($M_c = 9700 \text{ g mol}^{-1}$ – 5700 g mol^{-1} for hydrogels with 60 wt% BA and 1 wt%–2.5 wt% TPT, respectively).

The type of cross-linking agent also has an important effect on the mechanical properties of the hydrogels. Thus, copolymeric hydrogels of NIPA and AA^[35] have better mechanical properties when they are cross-linked with BIS, than with glyoxal bis(diallyl acetal) (GLY). Therefore, for hydrogels with 10 mol% of AA, the compression modulus is 6.68 kPa when they are cross-linked with 2.5 mol% of BIS and 1.44 kPa when it is done with the same percentage of GLY. The compensation is that hydrogels cross-linked with GLY exhibit much higher swelling ratios.

The mechanical resistance of the hydrogels is, therefore, very variable, existing mechanically weak hydrogels such as alginate hydrogels ionically cross-linked with CaCO_3 in the presence of D-glucono- δ -lactone, whose compression modulus reaches a value of 175 kPa.^[50] However, others are significantly mechanically resistant, such as those formed of PVP / β -chitosan in the presence of glutaraldehyde^[51] or the semi-interpenetrating hydrogels based on poly(3-hydroxybutyrate) and net-PEG,^[52] whose

tensile strength is 43.13 MPa and 350.6 MPa, in the dry state, respectively. Hydrogels of poly(vinyl alcohol) (PVA) called SalubriaTM^[53] have compressive modulus between 1 MPa and 18 MPa, and shear tangent modulus between 0.1 MPa and 0.4 MPa, which is within the range of the modulus of articular cartilage. Values of network parameters of different hydrogels are shown in Table 1.

BIOMEDICAL APPLICATIONS OF HYDROGELS

Hydrogels have numerous applications in the field of biomedicine because, as it has been previously indicated, their characteristics can be modulated in terms of their composition and preparation method. This way, matrices with elevated swelling levels can be obtained. In addition, they present mechanical properties which are suitable for a specific application, which along with their characteristics of being made up of biostable or biodegradable devices, it makes these elements very versatile and with very diverse applications, some of which are shown in the following paragraphs.

Contact Lenses and Ocular Implants

Soft contact lenses are one of the most widely used applications of hydrogels. One of the main characteristics of these lenses is their comfort because they perfectly adapt to the global ocular curvature, and furthermore they allow atmospheric oxygen to reach the cornea by dissolving in the water of the lens and then transported by diffusion, until reaching the permeability limits close to those of a hypothetical lens of distilled water. Studies carried out by the Tighe group^[21] show that there is a correlation between the equilibrium water content of a hydrogel and its permeability to oxygen; thus the copolymeric hydrogels of HEMA and VP with equilibrium water content of 80% have a high permeability to oxygen, somewhat higher than copolymeric hydrogels of HEMA–VP–styrene, whose equilibrium water content is around 70%.

The first contact lenses were developed at the beginning of the 1970s by Wichterle as a consequence of his work with hydrogels based on glycolmethacrylates.^[54] The first soft contact lenses marketed with real success were those made up of PHEMA, whose water content was 38%. Several companies subsequently developed a range of

Table 1 Network parameters of some hydrogels. ϕ_2 : volume fraction of polymer; ν_t : theoretical cross-linking density; ν_e : effective cross-linking density; E : Young's modulus; G : compression modulus; M_c : molar mass between cross-links; χ : polymer–water interaction parameter

VP: *N*-vinyl-2-pyrrolidone; PVP: polyVP; EGDMA: ethylene glycol dimethacrylate; BA: butyl acrylate; TPT: 1,1,1-trimethylolpropane trimethacrylate; NIPA: *N*-isopropyl acrylamide; AA: acrylic acid; BIS: *N,N'*-methylene bisacrylamide; PVA: polyvinyl alcohol; EDTAD: ethylenediaminetetraacetic dianhydride; PEGDA: polyethyleneglycol diacrylate; PETA: pentaerythritol triacrylate.

hydrogel lens materials containing various monomers such as VP, methacrylic acid (MAA), MMA, and glyceryl methacrylate (GM), among others,^[55,56] in the attempt of obtaining materials with an elevated water content and suitable mechanical properties, which allow them to resist the force of the eye lid, along with an elevated permeability to oxygen (Table 2). The permeability of oxygen is a very important factor when considering that hydrogel lenses can induce limbal hyperemia, which is a consequence of a localized hypoxia.^[57] It is considered that the oxygen transmissibility should be greater than $125 \times 10^{-9} \text{ Dk L}^{-1}$ in order to prevent stromal anoxia in the closed eye.^[58] This is achieved with hydrogel materials of high oxygen permeability such as silicone hydrogel lenses with values of Dk of 140 (Lotrafilon A—CIBA Vision).^[57]

The substitution of the crystalline lens for a transparent intraocular lens (IOL) has become an integral part of almost all cataract operations. Because the implantation of the IOL is done through a small incision, foldable lenses have been developed, some of which are PHEMA hydrogels (refractive index, 1.44; water content, 38%) or HEMA copolymers with MMA (refractive index, 1.47; water content, 20%) or with 6-hydroxyhexyl methacrylate (refractive index, 1.47; water content, 18%),^[59] because there is evidence that hydrophilic materials are less damaging to the corneal endothelium and produce lower levels of inflammatory response.

The vitreous humor of the eye is a hydrophilic gel with water content above 99%, formed by a network of collagen and hyaluronic acid, which in some pathological situations

becomes dysfunctional. For this reason, some hydrogels have been tested as substitutes for the vitreous humor of the eye, among them hydrogels of PVP, polyacrylamide (PA) and PVA, although no truly satisfactory result has been achieved.^[60]

Tissue Prosthesis and Tissue Regeneration

Among the applications of hydrogels as materials for tissue replacement, its possible use for replacing articular cartilage stands out. The importance of this use is obvious if we consider the millions of people who suffer from degenerative joint diseases, which make it necessary to have effective treatments available to repair cartilage damaged by pathological processes or from injuries. Among the possible treatments would be the replacement of the cartilage by arthroscopy, using a material that is similar to natural cartilage. This natural cartilage consists of a matrix of proteoglycans, able to retain water molecules due to the negative charges of the glycosaminoglycans present in their structure. These water molecules are eliminated from the matrix when it is exposed to pressure, this way cushioning the force exerted on it. For this reason, it can be considered that, from a practical point of view, the cartilage functions biomechanically as a specialized, physicochemically active biological hydrogel,^[61] and hydrogels can be used as model systems for quantitatively studying the influence of the intrinsic swelling parameter on the consolidation behavior, and thus obtain information on the fundamental parameters that control the biomechanical properties of the articular cartilage.

Table 2 Selected soft contact lens materials

Trade Name	Principal components	Water content (%)	Oxygen permeability (Dk)	Refractive index	Manufacturer
Optima FW	Polymacon (HEMA)	38.6	8.4×10^{-11}	1.43	Bausch & Lomb
Soflens66	Alphafilcon A (HEMA/VP/TBCM)	66	32×10^{-11}	1.39	Bausch & Lomb

HEMA: 2-hydroxyethyl methacrylate; VP: *N*-vinyl-2-pyrrolidone; TBCM: 4-*t*-butyl-2-hydroxycyclohexyl methacrylate; SVC: silicone vinyl carbamate; VA: vinyl alanine; NFMA: *N*-formylmethyl acrylamide; EDMA: ethylene dimethacrylate; MAA: methacrylic acid; MCOE-PC: 2-methacryloyloxyethylphosphorylcholine.

Regarding what was previously presented, it is understood that there is a clear interest in finding a material, with hydrogel characteristics, that can substitute polyethylene (PE), which is used in partial or total replacement of articular cartilage. For this reason, researchers at the University of Kyoto have studied hydrogels of PVA with mechanical characteristics and suitable lubrication because these hydrogels have a thicker fluid film under pressure than PE and also their wear factor is approximately five times higher than that of PE. In the *in vivo* studies, after maintaining the implants up to 52 weeks, no tissue degeneration was seen in the surrounding tissue^[62] and the biocompatibility with respect to the implants of ultrahigh molecular weight polyethylene (UHMWPE) seems to improve.^[63,64] Other researchers have come close to preparing a material that substitutes this tissue through the preparation of semi-interpenetrating hydrogels, with mechanical properties that are similar to those of cartilage.^[65] The mechanical characteristics of friction and wear of hydrogels of PHEMA have also been studied as possible substitutes of articular cartilage.^[66] However, the most promising hydrogels in this application seem to be those of PVA, prepared by freeze–thaw techniques,^[67] one of which is called Salubria[™]^[53] and its water content and mechanical characteristics are notably similar to those of articular cartilage.

Other studies are centered on the development of hydrogels that include helicoidal fibers of poly(ethylene terephthalate), in an attempt to simulate natural collagen fibers, in order to generate a material that has mechanical characteristics close to those of the ligaments and can be used as connective replacement tissue.^[68]

Hydrogels are also used as breast prostheses, due to their swelling characteristics, which make them similar to live tissue. Medical follow-ups of implanted women indicate that these implants remain soft after 18–48 months.^[69] However, all the results are not equally concordant because breast prostheses with textured surfaces and filled with PVP hydrogel undergo a significant increase in volume when implanted in patients as a consequence of osmosis.^[70]

There is high interest in the use of hydrogels in the regeneration of the central nervous system (CNS). Therefore, chemically cross-linked PHEMA tubes have been synthesized by applying centrifugal forces, whose outer diameter is 2.4 mm and wall thickness is 40 μm –400 μm , which could be used for guided regeneration in the nervous system.^[71] On the other hand, the Woerly group has studied hydrogels as macromolecular networks that may act as extracellular matrices to induce tissue growth and organization during the healing process, thus promoting tissue restructuring and axonal regeneration in

the damaged CNS. They have studied the possibility of tissue replacement in the CNS by means of polymer–cell hybrid constructs in which dissociated cells are included within a stable three-dimensional polymer matrix with sufficient void volume for cell biomass accumulation and a sufficient surface area for cell growth.^[72] For this, they have used hydrogels of *N*-(2-hydroxypropyl) methacrylamide (HPMA) cross-linked with BIS, which contain collagen, in which embryonic neurons, neonatal astrocytes, and Schwann cells have been immobilized, which in most cases were viable and were differentiated within the polymeric matrices. Initial studies of implantation of these hydrogels in rat neocortex showed that the polymers did indeed interact with the host as evidenced by the migration of host nonneuronal cells into the gels.^[73] The inclusion of amino sugar or peptide sequences in this type of hydrogels increases their adhesion properties with host neural tissue, apart from experiencing vascularization and being infiltrated by host nonneuronal cells, such as astrocytes and macrophages; the presence of a high number of axons has also been detected.^[74] This type of hydrogels containing nervous tissue cells can be used for repairing and regenerating the CNS.

Tissue Engineering

The objective of tissue engineering is to develop parts of the body as alternatives for tissue and organ transplants. It is essential to have a scaffolding material that guides cellular adhesion, the growth and the formation of new tissues in this development. Recently, hydrogels have been explored as scaffolding materials for applications in tissue engineering.

Among the possible materials that can be used for the preparation of hydrogels used in tissue engineering are the polysaccharides. The formation of hydrogels based on polysaccharides can be achieved, in general, through hydrogen links or by ionic interactions. Hydrogels of agarose and chitosan are among the first, and hydrogels of alginates and carrageenans are among the second.^[75] Chitosan can be processed through freezing and lyophilizing chitosan–acetic acid solutions in suitable molds, in order to form porous structures that can be used in cell transplantation and tissue regeneration,^[76] because the size and the orientation of the pores can be controlled, and as a result the mechanical properties of chitosan scaffolds. One of the applications described for chitosan-based hydrogels is in cartilage tissue engineering.^[75] Alginate hydrogels ionically cross-linked with calcium carbonate, calcium sulfate, and D-glucono- δ -lactone have also been developed, which generate homogenous matrices, with

appropriate mechanical properties that allow the incorporation of cells, specifically osteoblasts, and their culture in three dimensions.^[50]

Another type of hydrogel is that of poly(ethylene oxide) dimethacrylate (PEODM), obtained by photopolymerization in the presence of 2-hydroxy-1-[4-(hydroxyethoxy)phenyl]-2-methyl-1-propanone as UV photoinitiator, which encapsulates chondrocytes and can be used as scaffolds for cartilage growth.^[77]

With the aim of increasing cellular adhesion or helping a biospecific cellular adhesion, synthetic biomaterials modified with peptide sequences that constitute ligands of cellular adhesion have been prepared.^[78] Following this strategy, hydrogels of polyethylene glycol diacrylate with acryloyl-polyethylene glycol-RGDS have been synthesized, where RGDS is a peptide, which include TGF- β 1 (transforming growth factor- β 1) conjugated with PEG, because TGF- β increases the production of extracellular matrix proteins by vascular smooth muscle cells. The smooth muscle cells from the thoracic aorta of rats included in the PEG-based hydrogel grow better in this type of hydrogels, compared to those that lack TGF- β . Furthermore, this compound significantly improves the mechanical properties of the hydrogel.^[79]

The use of hydrogels in the preparation of scaffolds for other applications such as dental pulp tissue replacement^[80] or mandible condylar reconstruction has also been tackled.^[81]

Biosensors

Hydrogels are used in the preparation of biosensors, acting as supports for the immobilization of enzymes. The Veronese group has prepared diverse biosensors for enzyme immobilization, one of them being an amperometric sensor constructed by using PEG-modified glucose oxidase immobilized in a PVA cryogel membrane, obtained by a freezing–thawing cyclic process. This sensor allows for the determination of glucose electrochemically by measuring the hydrogen peroxide production as a result of the enzymatic reaction, which can be used in the determination of serum glucose.^[82] Likewise, considering the clinical interest in determining acetylcholine, they have developed a specific biosensor through the immobilization of acetylcholinesterase and choline oxidase (as PEG-modified choline oxidase) in a PVA cryogel membrane. This biosensor allows amperometrical determination of the hydrogen peroxide formed after the hydrolysis of acetylcholine by the acetylcholinesterase, which produces choline, in which the choline oxidase acts on generating hydrogen peroxide.^[83] The PEGylation step

is the critical step to increase the enzyme size needed to improve retention inside the gel and to convey at the same time the solubility of the enzyme inside the matrix. This fact is also confirmed in the immobilization of lipase, previously conjugated with PEG, in PVA hydrogels, designed for biocatalytic applications.^[84]

Because the determination of hydrogen peroxide is in itself of interest, hydrogel-modified graphite electrodes have been prepared through the inclusion of diverse redox enzymes in hydrogels of poly(vinylimidazole) complexed with Os(4,4'-dimethylbipyridine)₂Cl cross-linked with poly(ethylene glycol) diglycidyl ether (PEGDGE), as biosensors for the detection of hydrogen peroxide. Of all the biosensors prepared, the most sensitive H₂O₂ biosensor was that contained the newly purified sweet potato peroxidase.^[85]

Another compound whose measurement is of interest in clinical and forensic laboratories, as well as in food and beverage industries, is ethanol. Hydrogels of poly(carbamoyl)sulfonate (PCS) have been used for the immobilization of alcohol oxidase in order to make a biosensor that acts as an amperometric transducer for the detection of alcohols.^[86]

Wound Dressings

Hydrogels are used to aid in the regeneration of ulcerous and burn wounds because they create a permanent moist medium in the wound, therefore, stimulating the cellular activity in all the stages of the cicatrization process. Furthermore, they absorb exudation and secretions. The moist atmosphere created by the hydrogel softens and detaches the necrotic tissue, helping tissue regeneration in the granulation stage, absorbing the secretions, and creating a favorable atmosphere for the division and cellular activity of the epithelial tissue. At the same time, this type of dressing does not adhere to the wound, which is an advantage for the patient. Likewise, they prevent bacterial contamination of the wounds, being able to even incorporate some type of antibiotic, and furthermore they are permeable to oxygen. To attain satisfactory conditions at the wound site, the dressing should possess a suitable water vapor transmission rate.^[87] Studies carried out with experimental animals confirm that wound dressing based on hydrogels induced a significantly enhanced healing rate in the impaired wound.^[88]

Several laboratories have marketed hydrogel-type dressings (Table 3), all of them characterized by their high water content, greater than 95% in weight in some cases. In terms of their composition, there is a wide variety, they consist of: polyurethane, polyacrylate, polyacrylamide and agar, cross-linked polymers derived from acry-

lates substituted with groups of amine and nitrile, chitosan and PVP, as well as with derivatives of hyaluronic acid with or without alginates.

Dressings prepared from gelatine sponges that incorporate epidermic growth factor (EGF) are being studied, to help cellular proliferation and the epithelial regeneration process, and that are situated between elastomeric polyurethane membranes. The *in vivo* studies in rabbits indicate that these dressings provide a higher degree of reduction in the wound areas.^[89] Wound dressings with antimicrobial compounds have also been prepared; this wound dressing has the capacity to absorb the wound exudates thanks to its layer of carboxymethyl-chitin hydrogel, while its antimicrobial capacity resides in the chlorhexidine gluconate impregnated in a layer of chitosan acetate foam.^[90] Other wound dressings are made up of cross-linked hydrogels formed from blends of PVP with PEG and agar.^[91] Polyvinyl alcohol and PVP blended hydrogels,^[92] as well as PEO and PEO/PVA blend hydrogels^[93] for wound dressings have also been prepared. Poly(2-hydroxyethyl methacrylate)-based artificial skin for advanced wound dressing usage through the inclusion of weaved and knitted fabrics and fibers in soft PHEMA matrix has also been prepared.^[94]

Drug-Delivery Systems

The efficacy of the drug of a pharmaceutical product depends, to a large extent, on its dosage form, in other words, on its bioavailability. Currently, it is generally accepted that the pharmacological activity of a compound is not, in itself, enough to ensure a good therapy, but an

optimal therapeutic effect depends on appropriate dosage systems, on the type of formulation, and on the selection of a specific release system for the drug.

The efficacy of a drug in a specific application requires the maintenance of some appropriate concentration levels (generally plasmatic) of this compound during a prolonged period of time. However, the conventional administration of drugs gives, in most cases, a very poor control of the concentration of these substances in plasma, because they give rise to variations in the concentration of the bioactive product once a specific dose has been applied. The conventional dosage systems can give rise to alternative periods of inefficacy or toxicity. These difficulties have called for the development of new administration techniques for bioactive compounds, directed towards attaining that with a single dose the concentration of the drug in the organism (or even better in their target) is maintained out of the extreme limits of inefficacy and toxicity, during the appropriate period of time.^[95]

Drug-delivery systems allow the release of a drug during a dilated period of time or at a specific moment in the treatment. Furthermore, through these systems, the drug can be released in its target in the organism, being able to decrease its side effects and also prevent biological barriers that stop it from acceding the target.^[96] Among the possible drug-delivery systems, hydrogels have been extensively studied as drug-delivery devices^[96,97] due to their excellent capacity of absorbing water and their swelling and permeability characteristics that enable them to undergo structural changes in response to different physical, chemical, or biological stimuli,^[97,98] for which they have been named “intelligent” or stimuli-responsive drug-delivery systems.

Table 3 Selected wound dressing materials

Trade name	Principal components	Manufacturer
Tenderwet	Polyacrylate	Hartmann
Hidrosorb	Polyurethane	Hartmann
Geliprem	Polyacrylamide/agar	Inibsa
Hyflex	Hypan [®] (acrylate derivatives composed of several sequences of units with pedant hydrophilic groups and several sequences of units with pedant nitrile groups)	Hymedix
Aquatix II	Chitosan derivatives /PVP, polyethylenimine/PVP	Hydromer
Clear Hydrogel Films	Polysaccharide-based hydrogels	Veraco International
Hyalofill	Hyaff (hyaluronic acid-based hydrogels)	Convatec, S.A.
Jaloskin	Hyaff	Convatec, S.A.
Hyalogran	Hyaff	Convatec, S.A.
Hyalgin	Hyaff	Convatec, S.A.

General characteristics

Hydrogels loaded with an active substance are especially useful in the administration of this substance in accessible regions of the organism, such as the buccal, nasal, and vaginal region, as well as for oral or transdermal administration. They can also be placed subcutaneously or in the environs of the target of the bioactive compound, through a surgical incision.^[97]

The inclusion of a drug or active substance in a hydrogel can be carried out in two ways. One of them is through physical methods, introducing the dry gel (xerogel) in a concentrated solution of the drug, followed by the dehydration of the hydrogel once it has reached the swelling equilibrium,^[14,15] in other words, by equilibrium partitioning; or, if the drug is stable enough in the required synthesis condition, including it in the initial polymerization feed mixture, in order to, this way, directly obtain the gel loaded with the drug.^[17] The second form of inclusion of a substance in a hydrogel uses chemical mechanisms, consisting of the immobilization of the substance in the hydrogel matrix through the formation of ester, anhydride or amide type bonds that are later hydrolyzed in aqueous medium, this way getting the release of the drug.^[99]

The release of a drug dispersed in a hydrogel, which is initially in a dehydrated state (xerogel), is produced through the diffusion of the drug from and through the polymeric matrix, initially in a glassy state, by diffusion to the crosscurrent of water or biological fluids.^[100] When the xerogel loaded with the drug is put in contact with the aqueous medium, the water penetrates the matrix and the gel begins to swell, decreasing the glass transition temperature of the polymer and reaching a rubbery state, which increases the permeability of the polymer to the drug and allows it to spread to the exterior.^[101]

In order to interpret the kinetics of swelling of a hydrogel, as well as the release of a drug from a hydrogel, the concept of that sorption of water into glassy hydrogels generally exhibits anomalous behavior ranging from Fickian to Case II diffusion has been used. Fickian and non-Fickian behavior, for swelling as well as for drug release, depends on the rate of polymer relaxation at the glassy–rubbery transition at the swelling interface. To characterize the various types of solute diffusion in polymers, the following equation can be used, for at least the short-time period:^[101]

$$M_t/M_\infty = kt^n$$

where M_t and M_∞ are the mass of water taken up at time t and infinite time in sorption experiments, respectively.

In drug release experiments, M_t and M_∞ are the amounts of drug released at time t and the maximum amount of drug released, respectively, k is a constant which incorporates the structural and geometrical characteristics of the device, and n is the diffusional exponent that determines the release mechanism. For devices with slab geometry, $n = 0.5$ represents a Fickian diffusion mechanism, in this case the drug release is controlled by diffusion; while that when $n = 1$ the drug release is independent of time, and corresponds to a zero-order kinetics, and is called Case II transport. In this case the drug release is controlled by swelling. Values of n between 0.5 and 1 correspond to an anomalous transport, which indicates that the drug release is produced by mechanisms controlled by diffusion as well as by swelling. In the case of polymeric devices with geometries in the shape of a sphere or cylinder, $n = 0.43$ (sphere) or 0.45 (cylinder) indicates Fickian diffusion, while $n = 0.85$ (sphere) or 0.89 (cylinder) corresponds to drug release mechanism of Case II transport; the anomalous transport would be indicated by intermediate values of n .^[102]

Another criterion for predicting if the transport in polymeric gels is controlled by diffusion (Fickian) or by relaxation, is to determine the diffusional Deborah number (De), which is a ratio between the characteristic polymer relaxation time of the polymer (λ) when it is subject to a swelling stress and a characteristic diffusion time (θ), defined as the coefficient between the square of the sample thickness (h) and the coefficient of water diffusion in the polymeric gel (D):^[103]

$$De = \lambda/\theta = \lambda/(h^2/D)$$

If the swelling process is controlled by the relaxation time ($De \gg 1$) or by water diffusion ($De \ll 1$), the diffusion is Fickian. However, if $De \approx 1$, both processes will be produced simultaneously and it will be an anomalous transport.

Another parameter that indicates the characteristics of diffusion in polymers is the swelling interface number (Sw), a dimensionless number that describes the balance between solvent penetration and drug release:^[103]

$$Sw = v\delta/D$$

where v is the velocity of the moving glassy/rubbery front, δ is the thickness of the swollen gel layer, and D is the diffusion coefficient of drug in the polymer. When $Sw \gg 1$ the swelling front advances more quickly than the drug release, for which the release is Fickian. On the contrary, values of $Sw \ll 1$ indicate a zero-order release, since the transport speed of the drug through the solvated region

is quicker than the speed of the glassy–rubbery front. When $Sw \approx 1$ anomalous behavior prevails.

When the systems have a Fickian diffusion, the solution of the differential form of Fick's Law, considering one-dimensional diffusion from a very thin gel phase with slab geometry and a constant diffusion coefficient D , is:^[104]

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2 \pi^2} \exp\left(\frac{-D(2n+1)^2 \pi^2 t}{h^2}\right)$$

where h is the thickness of the dry hydrogel and t is the time.

This equation can be approached for early and moderate times of diffusion through the reduced expression:

$$M_t/M_\infty \approx 4(Dt/\pi h^2)^{1/2}, \quad M_t/M_\infty \leq 0.6$$

One criterion of Fickian behavior holds that M_t/M_∞ vs. $t_{1/2}$ plot should be linear up to 60% reduced sorption.

Diffusion coefficients can also be calculated from the late-time approximation:

$$M_t/M_\infty = 1 - [(8/\pi^2) \exp(-\pi^2 Dt/h^2)],$$

$$M_t/M_\infty \geq 0.4$$

This equation is more appropriate for determining drug diffusion coefficients of high-molecular-weight drugs.^[105]

Values of the diffusional exponent n close to 0.50 have been determined for the swelling of hydrogels of poly(2-hydroxyethyl methacrylate-*co*-acrylamide) [p(HEMA-*co*-A)],^[34] as well as for poly(2-hydroxyethyl methacrylate-*co*-methyl methacrylate) [p(HEMA-*co*-MMA)],^[105] among others. In general, the increase of the hydrophilic monomer in a copolymeric hydrogel gives rise to higher diffusion coefficients, which indicate a faster swelling as, for example, hydrogels with 80 wt% of HEMA and 20 wt% of A, cross-linked with 5 wt% of EGDMA, have diffusion coefficients for saline solution (NaCl, 0.9 wt%) uptake of $9.27 \times 10^{-11} \text{ m}^2 \text{ sec}^{-1}$ ($9.27 \times 10^{-7} \text{ cm}^2 \text{ sec}^{-1}$), while that for hydrogels of 60 wt% HEMA and 40 wt% A, with the same percentage of cross-linking agent, the diffusion coefficient is of $15.0 \times 10^{-11} \text{ m}^2 \text{ sec}^{-1}$ ($15.0 \times 10^{-7} \text{ cm}^2 \text{ sec}^{-1}$).^[34] The increase of the hydrophobic monomer (MMA) in copolymeric gels of p(HEMA-*co*-MMA) decreases the value of the diffusion coefficient for water uptake, whose values are $3.03 \times 10^{-7} \text{ cm}^2 \text{ sec}^{-1}$ for the samples with 75 mol% of HEMA, and $1.78 \times 10^{-7} \text{ m}^2 \text{ sec}^{-1}$ for those with 60 mol% of HEMA.^[105]

Drug release from a hydrogel is determined by the physical and chemical characteristics of the polymeric

matrix and by the nature of the drug included. In general, the increase of the hydrophilic monomer in a copolymer helps the drug release,^[34] and the decrease of the pore size of the matrix, produced by an increase of the cross-linking, slows the release, which results in smaller values of the diffusion coefficient of the drug.^[33] The chemical nature of the drug also conditions those diffusion coefficient values. Thus, for example, the release of cytarabine from hydrogels of poly(acrylamide-*co*-monomethyl itaconate) [p(A-*co*-MMI)], specifically from the 75A/25MMI composition, has diffusion coefficient values of $8.25 \times 10^{-11} \text{ m}^2 \text{ sec}^{-1}$,^[106] while the diffusion coefficient for the release of 5-fluorouracil, from the same hydrogels is $13.3 \times 10^{-11} \text{ m}^2 \text{ sec}^{-1}$.^[107] A complete study of the effect of the size of different drugs in the value of their diffusion coefficient from different hydrogels has been carried out by the Peppas' group.^[105] Some drugs released from different hydrogels are shown in Table 4.

Stimuli-responsive devices

Because hydrogels can be synthesized from monomers that give them sensitivity to different environmental stimuli, this characteristic can be used to release drugs or bioactive compounds included in hydrogels in response to those stimuli.

One of the stimuli that a hydrogel can be sensitive to is temperature. Within this group, we find examples such as thermosensitive hydrogels of poly(acryloyl-L-proline-methyl ester) [p(A-ProOMe)] which have been used for releasing gentamicin, used in the treatment of infectious diseases, isoniazid, for the treatment of tuberculosis, and insulin, for the treatment of diabetes.^[41] Hydrogel shrinking or swelling was found to play a relevant role in high-molecular-weight drug release. Thus, in the case of insulin, the release is affected by the temperature-sensitive properties of the hydrogel. However, these properties do not permit the control of the release of compounds of low molecular weight, such as gentamicin or isoniazid from these hydrogels. There are other compounds that have also been released from thermosensitive hydrogels. Such is the case of streptokinase, an antithrombotic agent, from block copolymers of poly(*N*-isopropyl acrylamide) and poly-(methacrylic acid) (PMAA).^[108] Likewise, the hormone calcitonin has been included in poly(*N*-isopropyl acrylamide-*co*-butylmethacrylate-*co*-acrylic acid) hydrogel, which responds to changes of pH and temperature.^[109]

Some of the temperature-sensitive hydrogels are also pH sensitive.^[108,109] The pH sensitivity of the hydrogels is due to the presence of weakly acidic and/or basic functional groups on the backbone, and in many cases,

Table 4 Drugs released from different hydrogels

Hydrogel	Drug	Reference
Poly(2-hydroxyethyl methacrylate)	Thiamine HCl	[30]
	L-Ascorbic acid	[15]
	Cytarabine	[17,18]
	5-Fluorouracil	[22,23]
Poly(2-hydroxyethyl methacrylate- <i>co</i> -acrylamide)	5-Fluorouracil	[126]
	Cytarabine	[34]
Poly(2-hydroxyethyl methacrylate- <i>co</i> -methyl methacrylate)	Theophylline, triamterene, oxprenolol, buflomedil, vitamin B ₁₂ , inulin, myoglobin	[105]
Poly(2-hydroxyethyl methacrylate- <i>co</i> - <i>N</i> -vinyl-2-pyrrolidone)	Cytarabine	[33,127]
Poly[2-hydroxyethyl methacrylate- <i>co</i> - <i>N,N'</i> -dimethyl- <i>N</i> -methacryloyloxyethyl- <i>N</i> -(3-sulfopropyl) ammonium]	Sodium salicylate	[14]
Poly(methyl methacrylate- <i>co</i> -dimethylaminoethyl methacrylate)	Aminopyrine, caffeine, theobromine	[110]
Poly(ethylacrylate methyl methacrylate) (Eudragit)	Metoprolol tartrate	[117]
Poly(acrylic acid- <i>co</i> -acrylamide)	Methotrexate	[128]
Poly(acrylamide- <i>co</i> -monomethyl itaconate)	5-Fluorouracil	[107]
	Cytarabine	[106]
Poly(acrylic acid- <i>co</i> - <i>n</i> -alkyl methacrylate)	Theophylline, aminophylline	[16]
Modified polyacrylamide- <i>g</i> -guar gum	Diltiazem, nifedipine	[31]
Poly(acryloyl-L-proline-methyl ester)	Gentamicin, isoniazid, insulin	[41]
Poly(methacrylated inulin- <i>co</i> -bis(methacryloylamino) azobenzene- <i>co</i> -2-hydroxyethyl methacrylate)	Prednisolone	[124]
Poly(ethylene oxide)	Salicylic acid	[12]
Poly(ethylene glycol) diacrylate	Bovine serum albumin (BSA)	[25]
Chitosan	Capsaicin, nomivamide	[129]
Chitosan/poly(<i>N</i> -vinyl-2-pyrrolidone)	Amoxicillin	[45]

they have been designed for the release of substances in areas of the organism with characteristic pH values, such as the stomach, where the pH is very acidic, or the intestine whose pH is neutral or basic. Thus, diltiazem hydrochloride and nifedipine, two antihypertensive drugs, have been released from cross-linked hydrogels of polyacrylamide-grafted guar gum (pAAm-*g*-GG) in simulated gastric and intestinal pH conditions,^[31] observing that the release was faster in pH 7.4 than in an acidic medium. The diffusion characteristics of aminopyrine, caffeine and theobromide, all of them weak bases whose maximum solubility reaches pH 1.2, and that have different solubility in water, from p(MMA/DMA) hydrogels cross-linked with DVB,^[110] a polycationic hydrogel that is in a hydrated state at acid pH and is dehydrated and stiff at neutral pH, have also been studied. A pH-sensitive hydrogel whose maximum swelling produces low acidic conditions is the semi-interpenetrant gel based on chitosan/PVP,^[45] which has been studied as a device for releasing the antibiotic amoxicillin in the acidic conditions of the stomach.

Other hydrogels have been designed incorporating different compounds, generally enzymes, which allow

them to respond to specific molecules. Thus, hydrogels of poly(diethylaminoethyl-*g*-ethylene glycol) [p(DEAEM-*g*-EG)] that contain immobilized glucose oxidase, which gives them glucose sensitivity, have been synthesized. Catalase has also been immobilized in these gels, with the intention that it decreases the amount of hydrogen peroxide formed in the reaction of the glucose oxidase and the amount of available oxygen is increased for the formation of acid. The enzymes are active in the gels and produce an acidic environment in the hydrogel, which causes the swelling of the polymeric matrix.^[111] The aim of these systems is to achieve a feedback-controlled release of insulin, in such a way that it can control the release of insulin absorbed in the gels through changes in their swelling modulated by glucose.

Other systems have been designed that respond, for example, to calcium, such as in the case of a starch-cellulose matrix that contains α -amylase, and whose degradation is produced in the presence of calcium, which allows the release of the drugs incorporated in the matrix.^[112] Hydrogels based on PVA that release antibiotics only in the presence of infection, due to the fact that they are thrombin sensitive,^[113] have also been

synthesized. Another system for the release of drugs or bioactive substances consists of an antigen-responsive hydrogel formed by an antibody-grafted linear polyacrylamide and the cross-linked polyacrylamide grafted with the corresponding antigen.^[114]

Routes of drug delivery

The aim of many of the hydrogels that have been designed for controlled drug release is to have their administration through different routes, for example, oral, nasal, vaginal, subcutaneous, or transdermal.^[97]

The oral administration of drugs through hydrogels is one of the routes that has aroused the most interest among researchers, who have tackled this form of administration, mainly through two strategies.

Mucoadhesive hydrogels. One of these strategies is the development of mucoadhesive hydrogels^[115] that interact with the mucus as a result of physical entanglement and secondary bonding, mainly through hydrogen bonding and van der Waals forces, due to the presence of hydroxyl, carboxyl, amine, and amide groups in the surface of the polymeric matrix,^[116] this way prolonging the residence time of the dosage form on the site of absorption.

The use of the buccal cavity for placing devices of controlled drug release allows it to avoid the first-pass metabolism and prevents the degradation of the drug in the gastrointestinal tract. With this aim, Eudragit buccal patches, a neutral copolymer of poly(ethylacrylate methylmethacrylate), with hydrophilic polymers that confer it bioadhesiveness, for the controlled release of metoprolol, a drug for the treatment of hypertension, have been prepared. The release of metoprolol is modified by the addition of hydrophilic polymers, due to their capacity of absorbing water.^[117]

Diverse materials that stimulate the bioadhesion with mucus have been studied. The bioadhesiveness of chitosan microspheres and starch microspheres has been studied through nasal administration in human volunteers, with the aim of characterizing them as bioadhesive nasal delivery systems. The studies indicate that chitosan delivery systems can reduce the rate of clearance from the nasal cavity, notably increasing the contact time between the release system and the nasal cavity.^[118] The adhesion characteristics of polyampholytic hydrogels formed by blends of deacetylated and *O*-carboxymethylated chitins have also been studied, observing that they are governed by the aqueous content of these hydrogels, those with a lower water content presenting greater adhesion strength.^[119]

The bioadhesive properties of hydrogels of poly(*N,N*-dimethylaminoethyl methacrylate-*co*-methyl methacrylate) [p(DMA/MMA)] cross-linked with DVB have been studied in vitro using pig gastric, sublingual, vaginal, and intestinal mucus. These hydrophobic polybasic gels have good adhesive properties in all of the mucus studied, which makes them candidates for the controlled release of drugs in these places.^[120]

Due to the turnover of the mucus gel layer of the mucus surface, which in some tissues such as the intestine is very fast, the adhesion of mucoadhesive devices of drug release is more difficult. This fact, along with the nonspecificity of adhesion of these devices has caused this to be researched in the development of release systems that include lectins and lectin-like molecules, which can directly interact with the cellular membrane in such a way that a cytoadhesion independent of mucus turnover is produced.^[121]

Sensitivity to pH changes. The second strategy developed for the oral administration of drugs through hydrogels is based on their sensitivity to changes in pH in different areas of the digestive tract,^[31,45,110,122,123] which allows them to swell to acid or neutral pH and to release the bioactive compound in areas such as the stomach or intestine.

Another approximation to make the oral administration of drugs through hydrogels specific has consisted of the design of drug release systems in the colon, taking advantage of the presence of specific bacteria, which form part of the bacteria flora, in this region. These bacteria secrete enzymes capable of hydrolyzing some polysaccharides, such as dextrano or inulin, and they are also able to reduce azo-compounds. These azo-inulin and azo-dextran gels can be hydrolyzed specifically by inulinase and dextranase, respectively, in the colon.^[124,125]

Another route of drug administration using hydrogels is done through subcutaneous implantation. In this case, the amount of water of the hydrogel is an important factor when considering its biocompatibility, because the greater the amount is, the more similar the hydrogel is to the individual's tissues. The presence or not of a thin fibrous capsule around the hydrogel discs implanted subcutaneously largely depends on their water content in the swelling equilibrium, which also affects the period of time necessary to its formation.^[126] When the drugs are administered through hydrogels subcutaneously, their plasmatic half-life is notably increased. Thus, for example, the administration of 5-fluorouracil through hydrogels of p(HEMA-*co*-A), cross-linked with EGDMA, increases the half-life of the drug 98 times ($t_{1/2} = 25.11$ hr), compared to its administration by intraperitoneal injection ($t_{1/2} = 0.257$ hr).^[126] An equivalent behavior is noticeable

when the antineoplastic cytarabine is administered subcutaneously through its inclusion in hydrogels of PHEMA and poly(2-hydroxyethyl methacrylate-*co*-*N*-vinyl-2-pyrrolidone) [p(HEMA-*co*-VP)] cross-linked with EGDMA, because its presence is detected in plasma between 4 and 16 days, despite the fact that the plasmatic half-life of it is 2.6 hr when it is administered by injection.^[127]

The administration of drugs through the skin through transdermal release from hydrogels means an advantage in the treatment of some illnesses. Thus, the iontophoretic delivery of methotrexate from hydrogels of AA and its copolymers with acrylamide has been studied, because this antineoplastic is used in the treatment of psoriasis. These hydrogels seem to be suitable for the topical administration of methotrexate, which would prevent secondary effects, fundamentally hepatotoxic, which are caused when it is administered orally.^[128] Other drugs included in hydrogels, whose transdermal administration has been studied, are capsaicin and nonivamide, which are used topically in the treatment of rheumatoid arthritis.^[129] Likewise, chitosan-based transdermal drug-delivery systems have been designed for releasing propranolol hydrochloride,^[130] a drug that is used in the treatment of tachycardia, trembling, and cardiac arrhythmias.

Hydrogels can be synthesized with a wide variety of characteristics, obtaining biostable as well as biodegradable polymeric matrices, whose mechanical properties and degree of swelling fit with a specific application. This makes them a group of materials with a wide and diverse spectrum of uses, which gives them a promising future in the field of biomedicine.

INTRODUCTION

Hot-melt extrusion is one of the most widely applied processing techniques in the plastics industry. Joseph Brama invented the extrusion process for the manufacturing of lead pipes at the end of the eighteenth century. However, hot-melt extrusion was not applied in the plastics' industry until the mid-nineteenth century, when it was first introduced into a wire insulation polymer coating process. Today, hot-melt extrusion is not only widely applied in the production of polymeric articles but also in polymer production and compounding. Currently, more than half of all plastic products, including plastic bags, sheets, and pipes, are manufactured by this process (1).

For pharmaceutical systems, several research groups have recently demonstrated that the hot-melt extrusion technique is a viable method to prepare granules, sustained release tablets, and transdermal and transmucosal drug delivery systems. Molten thermoplastic polymers during the extrusion process can function as "thermal binders and/or drug release retardants" once they exit the extruder and solidify. For film processing, a polymer can be shaped into a film via the heating process rather than through the traditional solvent-cast technique.

For pharmaceutical applications, hot-melt extrusion offers many advantages over traditional processing techniques. The advantages are as follows: 1) neither solvents nor water are used in this process; 2) fewer processing steps are needed, and, thus, time-consuming drying steps are eliminated; 3) there are no requirements on the compressibility of the active ingredients, and the entire procedure is simple, continuous, and efficient; 4) the intense mixing and agitation during processing cause suspended drug particles to de-aggregate in the molten polymer, resulting in a more uniform dispersion of fine particles; and 5) the bioavailability of the drug substance could be improved when it is dispersed at the molecular level in hot-melt extruded dosage forms. To produce the

pharmaceutical dosage forms via hot-melt extrusion, a pharmaceutical grade polymer must be selected that can be processed at a relatively low temperature due to the thermal sensitivity of most drugs. All components must be thermally stable at the processing temperature during the short duration of the heating process.

PROCESS AND EQUIPMENT

Hot-melt extrusion equipment consists of an extruder, downstream auxiliary equipment, and other monitoring tools used for performance and product quality evaluation (2). The extruder is typically composed of a feeding hopper, barrel, screw, die, screw driving unit, and a heating/cooling device. A diagram of a typical extruder is shown in Fig. 1. Downstream equipment is used to collect the extrudates prior to further processing. Monitoring devices on the equipment include temperature gauges, a screw speed controller, an extrusion torque monitor, and pressure gauges.

During the hot-melt extrusion process, different zones of the barrel are preset to specific temperatures before the extrusion process. A blend of the thermoplastic polymers and other processing aids is then fed into the barrel of the extruder through the hopper. The materials are transferred inside the heated barrel by a rotating screw. Temperatures at different sections of the barrel are normally controlled by electrical heating bands, and the temperature is monitored by thermocouples. The materials inside the barrel are heated mainly by the heat generated due to the shearing effect of the rotating screw and the heat conducted from the heated barrel. The molten mass is eventually pumped through the die, which is attached to the end of the barrel. The extrudates are then subject to further processing by auxiliary downstream devices.

During a continuous extrusion process, the feed stock is required to have good flow properties inside the hopper.

Fig. 1 Schematic diagram of a single-screw extruder. (From Ref. 11.)

For the material to demonstrate good flow, the angle between the side wall of the feeding hopper and a horizontal line needs to be larger than the angle of repose of the feed stock. In the case of cohesive materials or for very fine powders, the feed stock tends to form a solid bridge at the throat of the hopper, resulting in erratic powder flow. For these situations, a force-feeding device is sometime used.

The design of the extrusion screw has a significant influence on the efficiency of the hot-melt extrusion process. The function of the screw is to transfer the material inside the barrel and then to mix, to compress, and to melt the polymeric materials and to pump the molten mass through the die. Several parameters are used to define the geometrical features of the screw (Fig. 2).

Most screws are made from stainless steel that is surface-coated to withstand friction and potential surface erosion and decay that may occur during the extrusion process. Based on the geometrical design and the function of the screw at each section, an extruder is generally divided into three zones: feeding section, melting or compression section, and metering section, as seen in Fig. 1. Only single-screw extruders were used during the early days of this technology. Twin-screw extruders were invented in the late 1930s. The two screws can either rotate in the same direction (co-rotating extruder) or in the opposite direction (counter-rotating screw). Twin-screw extruders possess many advantages when compared to single-screw extruders, such as easier material feed, more intensive mixing, less tendency to overheat the materials, and a shorter residence time.

The purpose of the feeding section is to compact and to transfer the feed stock into the barrel of the machine. The channel depth (Fig. 2) is normally greatest in this section.

The performance of the feeding section depends on the external friction coefficient of the feed stock at the surface of the screw and barrel. The friction at the inner surface of the barrel is the driving force for the material feed, whereas the friction at the surface of the screw restricts the forward motion of the material. A high friction coefficient in the barrel and a low friction coefficient at the screw surface would contribute to a more efficient transfer of the materials in the feed section. Other properties of the feed stock, such as bulk density, particle size, particle shape, and material compactability, can also have an impact on the performance of the feeding section. The transfer of the

Fig. 2 Geometrical diagram of an extruder screw: 1) diameter of the barrel (D_b): inside diameter of the barrel; 2) channel depth (H): distance from screw roots to barrel inner surface; 3) flight clearance ($\delta(r)$): the distance in between the flight and the barrel inner surface; 4) channel width ($W(r)$): distance in between two neighboring flights; and 5) helix angle ($\theta(r)$): angle formed in between the flight and the direction perpendicular to the screw axis.

material should be efficient in order to maintain an increase in pressure in the compression zone and the metering zone. The pressure rise in these zones should be high enough to provide an efficient output rate of the extrudate. It is also possible to finetune the barrel temperature at the feeding section in order to optimize the friction at the surface of the barrel. Inconsistent material feed may result in a “surge” phenomenon that will cause cyclical variations in the output rate, head pressure, and product quality.

The polymer will begin to melt once the material enters the compression section of the extruder. The temperature of the melting section is normally set at 30–60°C above the glass transition temperature of amorphous polymers or the melting point of a semicrystalline polymer.

Under typical processing conditions, polymer melts behave as pseudoplastic fluids. The viscosity of a pseudoplastic fluid is shear rate dependent and is described by the following power law (Eq. 1):

$$\eta = K \times \dot{\gamma}^{n-1} \quad (1)$$

where η represents the viscosity of the polymer melt; $\dot{\gamma}$ is the shear rate imposed on the polymer; K depends on the properties of the polymer and is an exponential function of the temperature; n is a constant (in the range of 0.25–0.9 for the polymer melt) and depends only on the properties of the polymer.

A minimum temperature of the barrel must be reached in order to extrude the polymer. Otherwise, the shear torque on the screw may overload the capacity of the driving unit due to the high viscosity of the polymer melt. The dependence of polymer melt viscosity on the temperature at a given shear rate follows the Arrhenius equation (Eq. 2):

$$\eta = K' \times \exp(Ea/RT) \quad (2)$$

In Eq. 2, K' is a constant, depending on the structure and the molecular weight of the polymer; Ea is the activation energy of the polymer for the flow process, and it is a constant for the same type of polymer; R is the gas constant; and T is the temperature in degrees Kelvin.

The heat conducted from the barrel contributes to the melting process. However, most of the heat is generated from viscous heat dissipation due to the shearing of the polymer melt. Viscous heat generation is a process of transforming the mechanical energy into the thermal energy of the polymer melt. The rate of heat generation per unit volume due to the viscous heat dissipation is calculated from Eq. 3:

$$\dot{E} = m \times \dot{\gamma}^{n+1} \quad (3)$$

where m is a constant, $\dot{\gamma}$ represents the shear rate, and n is the power law constant (3).

The efficiency of the melting process depends on the properties of the polymer and the geometrical design of the extruder. Generally, the melting process of polymers of low viscosities and high thermal conductivities is a more efficient process. Changes in the screw design are sometimes warranted to improve the melting process. A solidified plastic or polymer component may block the channel if the melting step is insufficient. This could also result in a “surge” of the extrudate.

Thermoplastic polymers primarily exist in a molten state in the metering section. The output rate of the extrudate is highly dependent on the channel depth and the length of the metering section of the screw. The metering section has a shallow channel. Similar to the feeding section, the relative motion between the stationary barrel and the rotating screw metering section results in a velocity vector in the down channel direction, are known as “drag flow.” However, the flow of the polymer melt down in the channel is restricted due to a pressure build-up in the die. This decrease in output rate of the polymer melt due to this pressure is called “pressure flow.” The total flow rate is the difference between the “pressure flow” and the “drag flow” (5).

The die is attached to the end of the barrel. The geometrical design of the die will control the physical shape of the molten extrudate. The cross section of the extrudate increases due to swelling as the molten mass exits the die. Due to its viscoelastic properties, the polymer melt is able to recover some of the deformation imposed by the screw inside the barrel during the extrusion. This is referred to as “die swelling.”

Hot-melt extrusion processing conditions depend on the chemical stability and physical properties of the thermal polymer such as molecular weight, glass transition temperature, and the melting point (in the case of a semicrystalline polymer). During the melt extrusion process, polymers are subjected to a mechanical shear stress imposed by the rotating screw and thermal stress due to the relatively high processing temperature. Under these stresses, polymeric materials may undergo physical chain scission, chemical depolymerization, or thermal degradation. Techniques, such as differential scanning calorimetry and gel permeation chromatography, are widely used to monitor the stability of the polymer under the melt extrusion process. In order to improve the stability of the polymer during the extrusion process, plasticizers, antioxidants, and other additives are often included in the formulation.

Different types of downstream processing equipment are necessary for the hot-melt extrusion process. For extruded film preparations, chill rolls are used to cool

down and control the film temperature before it is taken up by the roller. The thickness of the film can also be controlled by adjusting the rotating speed of the chill rolls. Control of the chill roll temperature also influences the properties of the film. When the extrudate is in a rod shape, it can be chilled through a water bath or a cooling air tunnel and cut into granules by a pelletizer.

MATERIALS USED IN HOT-MELT EXTRUSION

The materials used in the production of hot-melt extruded dosage forms must meet the same levels of purity and safety as those used in traditional dosage forms. Most of the compounds used in the production of hot-melt extruded pharmaceuticals have been used in the production of other solid dosage forms such as tablets, pellets, and transdermals. The materials used in hot-melt extruded products must possess some degree of thermal stability in addition to acceptable physical and chemical stability. The thermal stability of each individual compound and the composite mixture should be sufficient to withstand the production process.

Hot-melt extruded dosage forms are complex mixtures of active medicaments and functional excipients. The functional excipients may be broadly classified as matrix carriers, release modifying agents, bulking agents, and miscellaneous additives. The selection and use of various excipients can impart specific properties to hot-melt extruded pharmaceuticals in a manner similar to those in traditional dosage forms.

The properties of the active drug substance often limit the formulation and preparation options available to the pharmaceutical scientist in the development of an acceptable dosage form. Hot-melt extrusion offers many benefits over traditional processing techniques. This is a relatively new technique to the pharmaceutical industry. The process is anhydrous, thus avoiding any potential drug degradation from hydrolysis following the addition of aqueous or hydroalcoholic granulating media. In addition, poorly compactable materials can be incorporated into tablets produced by cutting an extruded rod, thus eliminating any potential tableting problems seen in traditional compressed dosage forms. As an initial assessment, the thermal, chemical, and physical properties of the drug substance must be characterized. Depending on the unique properties of the drug substance and the other excipients in the formulation, the drug may be present as undissolved particles, a solid solution, or a combination in the final dosage form. The state of the drug in the dosage

form may have a profound impact on the processability and stability of the product.

In addition to thermal degradation, the active compound may interfere with the functionality of the other components in the formulation. Oxprenolol hydrochloride was shown to melt under the hot-melt extrusion processing conditions, thus decreasing the viscosity of the extrudate to yield a material with poor handling properties (6). In similar work preparing dosage forms by injection molding, Cuff and Raouf (7) reported that fenoprofen calcium inhibited the hardening of a PEG–MCC matrix, thus resulting in an unusable product. Lidocaine was shown to effectively lower the T_g of Eudragit® E/HDPE films (8), and hydrocortisone demonstrated a time-dependent lowering of the glass transition temperature of hydroxypropylcellulose (HPC) films (9). These changes may be beneficial, as in the last two examples, or detrimental, as in the first two examples.

As mentioned previously, the drug may be present in one of several forms in the final product. The advantages and disadvantages of each form have been discussed in both injection molding (7) and melt extrusion (10) systems. Solid dispersion systems may be more stable and more easily processed than solid solution systems, but solid solution systems may be produced that are transparent and have increased bioavailability of poorly soluble compounds. Figs. 3 and 4 show the X-ray diffraction patterns for a polymer film containing lidocaine. The absence of the lidocaine peaks in the extruded samples, and the reported decrease in polymer T_g in these systems confirms that the drug exists in a solid solution within the film matrix.

In hot-melt extruded drug delivery systems, the active compound is embedded in a carrier formulation comprised of one or more meltable substances and other functional excipients. The meltable substances may be polymeric materials (6–12) or low melting point waxes (13, 14). The selection of an appropriate carrier compound is important in the formulation and design of a hot-melt extruded dosage form. The properties of the carrier material often dictate the processing conditions necessary for the production of the dosage unit, and the physical and chemical properties of the carrier often modulate the release of the active compound from the final dosage form. Table 1 lists some of the properties of various carrier compounds used in the production of hot-melt extruded dosage forms.

The use of polymeric carriers usually requires the incorporation of a plasticizer into the formulation in order to improve the processing conditions during the manufacturing of the extruded dosage form or to improve the physical and mechanical properties of the final product. The choice of a suitable plasticizer will depend on many

factors, such as plasticizer-polymer compatibility and plasticizer stability. Triacetin (6), citrate esters (8, 9), and low molecular weight polyethylene glycols (6, 9, 12) have been investigated as plasticizers in hot-melt extruded systems. As mentioned previously, certain drug compounds were reported to function as plasticizers in different hot-melt extruded systems (6, 8, 9). The plasticizer functions to reduce the glass transition temperature T_g of the polymer and to reduce the processing temperatures necessary for production. The reduction in polymer T_g is dependent upon the plasticizer type and level. Fig. 5 demonstrates the effectiveness of various plasticizers in lowering the T_g of hydroxypropylcellulose films. The reduction in processing temperatures may improve the stability profile of the active compound (9) and/or the polymeric carrier (6, 12). Plasticizers also reduce the shear forces needed to extrude a polymer, thus improving the processing of certain high molecular weight polymers (9, 12). Table 2 demonstrates the profound influence on the incorporation of PEG 3350 into hot-melt extruded tablets containing PEO (MW 1,000,000) and

Fig. 3 Wide angle X-ray diffraction scans of extruded Eudragit E films showing the effect of plasticizer and drug on the packing of polymer film. (From Ref. 8.)

Fig. 4 Wide angle X-ray diffraction scans of a physical blend of Eudragit E100 with 5 and 10% lidocaine HCL compared with lidocaine HCL crystals. (From Ref. 8.)

chlorpheniramine maleate. The incorporation of PEG 3350 into the carrier matrix reduces the temperatures necessary for processing and prevents the degradation of the polymer as noted by an equivalent molecular weight. The stability of a plasticized polymethacrylate system has been reported where the residual monomer content only increased 0.003% following extrusion using triacetin (6). Ethyl cellulose was also reported to be fairly stable following processing (11).

The thermochemical stability and volatility of the plasticizer during processing and storage must also be taken into consideration (9, 15–17). Table 3 illustrates these factors. Repka and McGinity demonstrated that the amount of plasticizer remaining in hot-melt extruded films over time was a function of the plasticizer type. The amount of plasticizer recovered in these films was compared to the initial theoretical amount added in all formulations. HPC films containing polyethylene glycol 400 and 8000 (PEG 400, PEG 8000), triethyl citrate (TEC)

Table 1 Properties of selected carriers used in the design and production of hot-melt extruded dosage forms

Chemical name	Trade name	Molecular weight range (s)	Melting point range (s)	Glass transition temperature	Reference
Polymeric carriers					
Ethylcellulose	Ethocel [®] Aqualon [®] EC	N-7 to N-100 based on viscosity	Decomposes at >190°C	130–133°C	6, 41
Hydroxypropyl cellulose	Klucel [®]	80,000–1,150,000	Chars at 260–275°C	Softens at 130°C	9, 42

and acetyltributyl citrate (ATBC) were tested at these two conditions: 25°C/0% RH and 25°C/50% RH for 1-week (initial), 3-month, and 6-month testing intervals. As can be seen from the results, both the citrate esters had a minimal loss at both testing conditions for the duration of the study. The most stable plasticizer for this 6-month study was PEG 8000. However, the lower molecular weight PEG had the greatest loss of any of the other three plasticizers investigated. At the more rigorous testing conditions of 25°C/50% RH, only 63% PEG 400 was detected in the HPC films for the duration of the study. These results indicate the tendency of PEG 400, and potentially other plasticizers, to evaporate or degrade under hot-melt extrusion processing and storage. It is also evident that these findings for PEG 400 explain changes upon mechanical testing of PEG 400-incorporated HPC films (9).

Plasticizers may also be incorporated into hot-melt extruded dosage forms to improve the physical–mechanical properties of the final dosage form. In transdermal films, the addition of a plasticizer to the polymer matrix can improve the film's flexibility (8, 9). Plasticizers may also influence the product's tensile strength and elastic modulus. In addition to the plasticizer's effect on the performance of hot-melt extruded polymer systems, the thermal history of the material may impact the properties of the final dosage form. The properties of high molecular weight polymers often depend upon the processing and storage conditions experienced prior to incorporation into the final dosage forms. Exposure to heat and/or moisture may influence the stability and processing of different batches of polymeric materials. There have been several reports on the influence

of heating and cooling on the physical and chemical properties of PEG-containing systems (16–21).

For systems employing nonpolymeric carrier materials, similar concerns must be addressed. The compatibility between the active substance and carrier should be addressed. The incorporation of a low-melting point compound into a low-melting point wax may result in the formation of a eutectic mixture or a reduction in the melting point of the material that may prevent the formation of a solid dosage form. The production of granules using carnauba wax has been reported (13, 14). The granules contained diclofenac sodium and could be produced at temperatures less than the reported melting point of the wax material. The use of waxes and wax-based materials may be advantageous due to their reported chemical inertness (13).

The drug release rate from hot-melt extruded dosage forms is highly dependent upon the characteristics of the carrier material. Most of the materials reported for use in hot-melt extruded dosage forms are water insoluble (6, 11, 13, 14) or have slow hydrating or gelling rates (9, 12). To improve or to modulate drug release from these systems, functional excipients may be added. Depending upon the physical and chemical properties of these additional excipients, various release profiles may be achieved. Follonier and coworkers (11) investigated a variety of compounds in several polymeric systems using diltiazem hydrochloride as a model compound. The additives were incorporated into the formulation in an effort to increase the drug release rate by increasing the porosity of the pellet during dissolution. Viscosity inducing agents were incorporated

Fig. 5 (a) Glass transition temperatures of HPC films containing PEG 8000 2%, TEC 2%, and ATBC 2% at 1 week, 3 months, and 6 months; (b) Glass transition temperatures of HPC films containing PEG 400 1%, HC 1%, and CPM 1% at 1 week, 3 months, and 6 months. (From Ref. 9.)

in the polymer matrix to limit the burst effect often seen with matrix systems. The use of ionic or pH-dependent polymers in the carrier matrix may allow for zero-order drug release or pH-dependent drug delivery. Swelling agents, such as AcDiSol[®] and Explotab were also investigated as a method to modulate drug release. In contrast, it has been demonstrated that Explotab could be used as a “super-absorbent” in HPC hot-melt

extruded films to facilitate moisture or exudate uptake in wound care applications (22). A similar approach of drug release modification was applied to wax containing systems (13, 14). Hydroxypropylcellulose, Eudragit L, and sodium chloride were incorporated into diclofenac sodium/carnauba wax matrices. Increasing the content of the cellulose derivative or methacrylic acid copolymer resulted in a substantial increase in the release of diclofenac sodium. The release of diclofenac sodium from hydroxypropyl cellulose/wax matrices was less pH dependent than the system containing wax/Eudragit L because the methacrylic acid copolymer is insoluble in water or in solutions with pH < 6. The effect of sodium chloride was less pronounced and was attributed to the negligible swelling effect of this material.

The properties of poly(vinyl acetate) as a carrier for theophylline from matrix dosage forms prepared by hot-melt extrusion has been investigated (23). The influence of granule size and drug loading level on the drug release properties was studied. The thermal stability of poly(vinyl acetate) was also investigated. In this study, Zhang and McGinity ground the rod shaped extrudates and then compressed them into tablets with various combinations of microcrystalline cellulose. The influence of granule size on the release rate of theophylline from the compressed tablets containing the hot-melt extruded granules is seen in Fig. 6. As the size of hot-melt extruded theophylline/PVAc granules was increased, there was a significant decrease in the release rate of the theophylline. Because the drug was released from the matrix by a diffusion mechanism, the decrease in the drug release rate from the tablets containing larger granules was concluded to be a result of a longer diffusion pathway. The influence of theophylline loading on the release properties of these tablets containing extruded granules is shown in Fig. 7. The PVAc was demonstrated to have a high solids carrying capacity when processed by hot-melt extrusion. It is important to note that a powder blend containing 50% theophylline could be readily processed utilizing this hot-melt technique.

These same investigators studied the stability of PVAc to shear stress using a Plasticorder[®] rheometer (23). As shown in Fig. 8, the initial peak indicated the heating process of the added PVAc. The torque gradually decreased as the temperature of the polymer melt in the chamber was increased. No further change in the torque was observed after the initial heating step. This finding confirmed that PVAc was not susceptible to degradation by either thermal or shearing stress under the processing conditions.

Other materials may also be included in the formulation of hot-melt extruded dosage forms. These miscellaneous compounds include embodying agents and antioxidants.

Table 2 Stability of polyethylene oxide (MW 1,000,000) in hot-melt extruded tablet formulations containing 6 wt% chlorpheniramine maleate processed at different temperatures

Formulation	PEO (wt%)	PEG 3350 (wt%)	Zone 1 temperature	Zone 2 temperature	Die temperature	Weight average MW	Standard deviation
1	94	0	100°C	115°C	130°C	710,000	50,000

**Fig. 6** Influence of the granule particle size on the theophylline release properties of the tablets containing hot-melt extruded granules ($n = 3$). Tablets: 20% extruded granules (Formula 3: 25% theophylline, 2% PEG, and 73% PVAc), 79.5% Avicel® PH 200, and 0.5% magnesium stearate (♦) Less than 125 μm ; (■) 180–212 μm ; (▲) 300–425 μm ; (○) 500–600 μm . (From Ref. 23.)

Cuff and Raouf (7) reported the incorporation of microcrystalline cellulose into PEG 8000 matrices in order to improve the formulation viscosity and plasticity of the resulting tablets formed by injection molding. Excessive temperatures needed to process unplasticized or underplasticized cellulose-based polymers (i.e., hydroxypropyl-cellulose or ethyl cellulose) may lead to polymer oxidation. One manufacturer of these materials recommends the incorporation of an antioxidant, such as butylated hydroxytoluene or ascorbic acid, into formulations containing low molecular weight hydroxypropyl-cellulose (24). Similarly, a combination of an antioxidant, light absorber, and acid acceptor is recommended for systems employing ethyl cellulose (25). Poly(ethylene oxide) films have been reported to be protected from free radical and oxidative degradation by the incorporation of an antioxidant (26).

The materials used in the production of hot-melt extruded dosage forms are the same pharmaceutical compounds used in the production of more traditional systems. Thermal stability of the individual compounds is a prerequisite for the process, although the short

Fig. 7 Influence of drug loading levels on theophylline release properties of the tablets containing hot-melt extruded granules ($n = 3$). Tablets: 20%, 300–425 μm extruded granules (Formule 1–4: theophylline, 2% PEG and PVAc qs to 100%), 79.5% Avicel PH 200, and 0.5% magnesium stearate. processing times encountered in this process may not limit all thermolabile compounds. The incorporation of plasticizers may lower the processing temperatures encountered in hot-melt extrusion, thus reducing drug and carrier degradation. Drug release from these systems can be modulated by the incorporation of various functional excipients. The dissolution rate of the active compound can be increased or decreased depending on the properties of the rate-modifying agent. For systems that display oxidative or free radical degradation during processing or storage, the addition of antioxidants, acid acceptors, and/or light absorbers may be warranted.

APPLICATIONS

For over two decades, the value of “continuous processing” in the pharmaceutical industry has been recognized. The potential of automation, reduction of capital investment, and the reduction in labor costs has made hot-melt extrusion worthy of consideration (27).

Conventional extrusion/spheronization is a significant process in obtaining controlled release pellets, as are solution/suspension techniques (28, 29). The quality of these pellets or granules is important, as was recognized by Gamlen et al. (10) and Lindberg et al. in the mid-1980s (30, 31). However, control of porosity, content uniformity, consistent pellet size distribution, as well as achieving a true continuous process, were not easily attained. Pellet technology has advanced in the 1990s with the advent of new processing equipment. Such developments have given the pharmaceutical scientist numerous opportunities to apply scientific principles to the design of novel dosage forms.

Until recently, hot-melt extrusion had not received much attention in the pharmaceutical literature. Pellets comprising cellulose acetate phthalate were prepared using a rudimentary ram extruder in 1969 and studied for dissolution rates in relation to pellet geometry (32). More recently, production of matrices based on polyethylene and polycaprolactone were investigated using extruders of laboratory scale (33, 34). Mank et al. reported in 1989 and 1990 on the extrusion of a number of thermoplastic polymers to produce sustained release pellets (35, 36). A melt-extrusion process for manufacturing matrix drug delivery systems was reported by Sprockel and coworkers (37). As one can see, a review of the pharmaceutical scientific literature does not elucidate many applications for hot-melt extrusion in this field.

Follonier and coworkers in 1994 investigated the possibility of using hot-melt extrusion technology to produce sustained-release pellets (6). Fig. 9 exhibits the ram extruder used in their investigations. Again, it was the researchers' goal to provide a product in a simple, single, and continuous manner. Thermal degradation was recognized as a limitation of this hot-melt process. Diltiazem hydrochloride, a relatively stable, freely soluble drug, was incorporated into their polymer-based pellets for sustained-release capsules. Prior to formulation, polymers and plasticizers were selected to optimize the possibility of a successful product. In this report, ethyl cellulose (EC), cellulose acetate butyrate (CAB), poly(ethyl acrylate/methyl-methacrylate/trimethyl ammonio ethyl methacrylate chloride) (Eudragit RSPM), and poly(ethylene-co-vinyl acetate) (EVAC) were the polymers utilized. Plasticizers used included triacetin and

Fig. 9 Schematic diagram of a laboratory ram extruder. (From Ref. 6.)

diethyl phthalate. The porosity of the formulations was assessed by mercury porosimetry. Pellets that were produced exhibited a rather smooth surface and low porosity, as demonstrated in Fig. 10. The *in vitro* release of diltiazem was biphasic, with the CAB and EVAC pellets giving the slowest release rate, as seen in Fig. 11, 12. They also found that the stability of Eudragit RSPM was adequate for extrusion at a temperature of 130°C. Not surprisingly, the type and percent of plasticizer used, drying time of the polymers, extrusion temperatures, and plasticization times varied with each formulation. In a latter study, Follonier et al. examined different parameters influencing the release of diltiazem hydrochloride from hot-melt extruded pellets (11). These parameters included polymer type, drug/polymer ratio, and pellet size. The authors also incorporated various polymer excipients into the pellet formulations to vary the drug release rate, such as croscarmellose sodium (Ac-Di-Sol®) and sodium starch glycolate (Explotab). These pellets could be applicable for incorporation into hard gelatin capsules. With optimization of techniques and formulations, it is apparent that hot-melt extrusion of these and other sustained-release pellets is a viable drug delivery technology.

Currently, the most frequent means of producing thin films for transdermal/transmucosal drug delivery and wound care is via film casting from organic or aqueous solvents (8). However, it is recognized that there are numerous problems with these types of films. For example, Gutierrez-Rocca and McGinity showed that physical aging of both aqueous- and solvent-cast acrylic films resulted in a decrease in elongation or elasticity and an increase in the tensile strength. The changes in the mechanical properties were related to a relaxation of the polymer chains toward a state of equilibrium (16). Also, it has been demonstrated that the type and level of

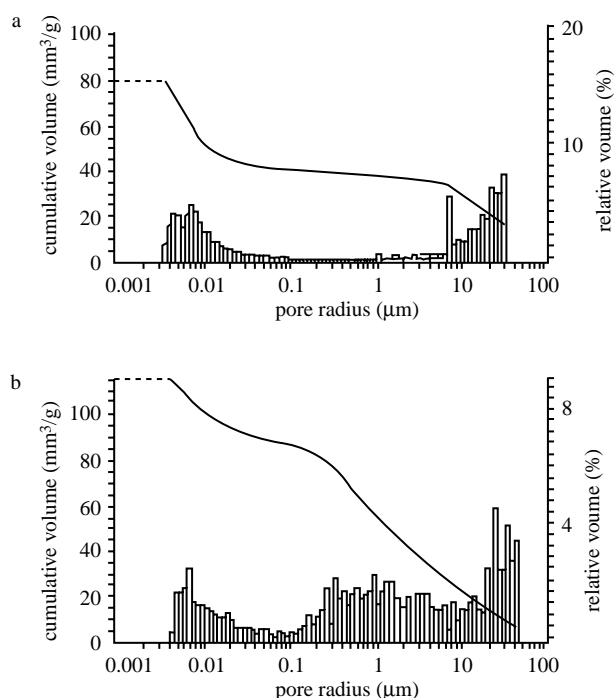

Fig. 10 Mercury infusion curves and pore size distributions of Eudragit RSPM (a) and Elvaxr 40W (b) based pellets containing diltiazem hydrochloride. (From Ref. 6.)

plasticizers, curing time, and temperatures will have a significant effect on the dissolution rate of drugs from films formed from aqueous dispersions (38–40).

Aitken-Nichol and coworkers investigated the viability of hot-melt extrusion technology in 1996 for the production of thin, flexible, acrylic films for topical drug

Fig. 11 Release profiles of diltiazem hydrochloride from extruded pellets based on various polymers (polymer/drug ratio: 1:1; size: 2 × 2 mm). (From Ref. 6.)

Fig. 12 Diltiazem hydrochloride released (%) as a function of the square root of time and calculated regression lines (—). (From Ref. 6.)

delivery (8). One of the advantages that the researchers pointed out was that the manufacturing process is not restricted by solvent concerns. Although a truly continuous operating mode was not utilized in this investigation, the potential for one definitely exists. The investigators compared a cast film with various extruded films. The data in Table 4 illustrate the effects of types and levels of plasticizers and model drugs used in this study on the glass transition temperature (T_g) and the mechanical properties of high density polyethylene (HDPE) and Eudragit E-100 extruded films. Eudragit E-100 was the primary thermoplastic polymer extruded. The authors found that

hot-melt extrusion was a viable technology for the production of free films of this acrylic resin. Although triethyl citrate was an acceptable plasticizer for this polymer, these researchers showed that lidocaine HCl was also able to plasticize the acrylic films. The authors concluded that the differences in the dissolution and ductile properties between cast films and extruded films were due to the amount of drug dissolved in the polymer. The dissolution rate of lidocaine HCl was affected by the drug loading, in contrast to the solvent-cast films tested.

Transdermal and transmucosal drug delivery systems are frequently produced by films cast from organic or aqueous solvents. Repka and coworkers discussed the numerous disadvantages accompanying these techniques, including long processing times, environmental concerns, and excessive costs (9). Hot-melt extrusion technology was used by these researches to produce HPC films utilizing a Killion extruder. Various plasticizers and two model drugs were incorporated into the HPC films. The influence of these plasticizers and drugs on the physical–mechanical properties of the films was investigated. The authors observed that a pure HPC film could not be produced without the incorporation of a plasticizer due to the high stress exhibited in the extruder. The results in Table 5 illustrate the effects of a number of conventional plasticizers and two model drugs on the three mechanical properties of HPC films. With the exception of PEG 400, all plasticizers investigated demonstrated adequate stability for the duration of the study. PEG 400, although initially exhibiting excellent plasticizer qualities for the HPC films, was found to be unstable in all parameters

(From Ref. 9.)

tested. The influence of processing temperature and storage time on the two model drugs was investigated and is outlined in Table 6. Besides the fact that CPM proved to be an excellent plasticizer for HPC, providing

mechanically stability for the hot-melt extruded film, it also proved to be chemically stable for up to 12 months. In addition, it was demonstrated by differential scanning calorimetry that CPM was fully dissolved in the HPC film

Table 6 Influence of processing temperature and storage at 25°C on percentage of chlorpheniramine maleate (CPM) and hydrocortisone (HC) remaining in HPC extruded films ($n = 6$)

(°C)	CPM (1 wk)	CPM (6 mon)	CPM (12 mon)
170	98.6 (1.6)	98.5 (1.9)	98.4 (1.9)
180	98.5 (1.9)	98.5 (2.1)	98.1 (2.4)
190	98.1 (2.2)	97.6 (2.7)	97.3 (2.5)

200	70.2 (3.8)	68.8 (3.3)	62.9 (3.1)

Standard deviations denoted in parenthesis.
(From Ref. 9.)

up to the 10% level (Fig. 13) (17). As can be seen, CPM is amorphous within the HPC film thus, a solid solution exists. Hydrocortisone was shown to be a good plasticizer comparable to that of the conventional plasticizers studied however, the chemical stability of HC incorporated into the HPC films was demonstrated to be a function of processing temperature and residence time in the extruder.

Repka et al. (9) also found an inverse relationship during film testing. All extruded films exhibited a marked decrease in tensile strength, in contrast to a large increase in percent elongation, when testing was performed perpendicular to flow vs. in-the-direction of flow, as seen in Fig. 14. This is in contrast to the findings of Aitken-Nichol et al. (8). These researchers reported a 25- to 35-fold increase in both tensile strength and percent elongation in a high density polyethylene/Eudragit E100 (50:50 polymer ratio containing 5% lidocaine HCl) extruded film when tested in the direction of orientation versus perpendicular to orientation (15). The differences between the findings in the two studies, however, may be explained by the poor compatibility of the two polymers. Such mechanical property differences illustrate the importance of "flow orientation" when designing delivery systems or wound care applications utilizing extruded films.

Vitamin E TPGS NF (D- α -tocopheryl polyethylene glycol 1000 succinate) has been utilized for numerous applications in pharmaceutical dosage forms. Its chemical structure contains both a lipophilic and a hydrophilic moiety, making it similar to a conventional surface-active agent. Due to TPGS's unique properties as a solubilizer,

Fig. 13 Differential scanning calorimetry profiles of hot-melt extruded films containing chlorpheniramine maleate and hydroxypropylcellulose: (a) chlorpheniramine maleate (CPM); (b) 10% CPM and 90% HPC (Klucel HF) physical mix; and (c) 10% CPM and 90% HPC (Klucel HF) extruded film. (From Ref. 17.)

Fig. 14 (a) Tensile strength of HPC films containing various plasticizers and drugs tested in direction of flow and perpendicular to flow; (b) Percent elongation of HPC films containing various plasticizers and drugs tested in direction of flow and perpendicular to flow. (From Ref. 9.)

absorption enhancer, and a potential controlled drug release vehicle, transdermal and transmucosal applications have been shown to be possible via hot-melt extrusion technology (41). Repka and McGinity prepared films containing hydroxypropylcellulose and polyethylene oxide (PEO) using a Randcastle extruder (Model # 750) with and without Vitamin E TPGS as an additive. As can be seen from Fig. 15, the addition of 1, 3, and 5% TPGS, respectively, decreased the glass transition temperature of the extruded films containing either a 50:50 or 80:20 ratio of HPC to PEO in an almost linear fashion. The presence of 3% Vitamin E TPGS lowered the T_g over 11°C when compared to the HPC/PEO 50:50 blend film without TPGS, thus functioning as a plasticizer. The films containing 3% Vitamin E TPGS had similar mechanical properties to that of the films containing 3% PEG 400 and a three-fold increase in percent elongation when compared to the films containing TEC 3% and ATBC 3%. In addition,

Fig. 15 Glass transition temperatures of films containing different levels of Vitamin E TPGS incorporated into two formulations of HPC/PEO hot-melt extruded films ($n = 4$). (From Ref. 41.)

the Vitamin E TPGS facilitated the processing of the HPC/PEO films by decreasing the barrel pressure, drive amps, and torque of the extruder equipment (Table 7). The unique properties of Vitamin E TPGS can function to promote more applications and opportunities in wound care and in transdermal and transmucosal drug delivery.

Another application of hot-melt extrusion was described by Zhang and McGinity (12). These researchers investigated the properties of polyethylene oxide (PEO) as a drug carrier and studied the release mechanism of chlorpheniramine maleate (CPM) from matrix tablets. In these extruded tablets, PEG 3350 was included as a plasticizer to facilitate processing. In this study, the stability of the primary extruded polymer, PEO, as a function of processing temperature was reported (Table 2). Again, polymer type, temperature, and residence time in the extruder was shown to be of great importance. These authors also reported that the drug, polymer, and other ingredients must be stable at the elevated processing

temperature during the approximately 2 min that the powder blend is processed through the equipment. In addition, the researchers showed that additional mixing of the components occurred in the barrel of the extruder, because the content uniformity of the extruded tablets was within 99.0–101.0% of the theoretical content. The profiles in Fig. 16 illustrate the influence of PEG 3350 on the release of CPM from the extruded matrix tablets. It can be seen that as the percent of PEG 3350 increases, the release rate of CPM increases. Polyethylene glycol is composed of the same structural unit as PEO but has a lower molecular weight than PEO. Thus, PEG 3350 hydrated and dissolved faster than the PEO. The hydration and dissolution rates of the entire matrix system were, thus, accelerated due to the presence of the plasticizer. The influence of drug loading on the release of CPM is shown in Fig. 17. When the drug content was increased from 6 to 12%, no change in the percentage of drug release with respect to time was observed. There was only a slight increase when the drug loading reached 20%. This study conveys the reproducibility of dissolution data for the tablets produced by hot-melt extrusion.

A bioadhesive hot-melt extruded film for intraoral drug delivery and the processing thereof has been patented (42,43). Applications of these films may be utilized in transmucosal drug delivery or even transdermal systems. The films may be produced separately and layered after extrusion, or in some cases, a multilayered system may be extruded in one continuous process. Currently on the market is an extruded film device that is utilized as a denture adhesive. This system includes thermoplastic polymers that have a bioadhesive quality when the film is wetted. Before application and wetting, however, this thin film may be held in one's hand and shaped or cut. This device is again produced by a one-step, continuous process using hot-melt extrusion technology.

A polymeric film that possesses inherent bioadhesive properties has the added benefit of simplifying the dosage

Table 7 Processing conditions for hot-melt extruded films containing a 50:50 ratio of hydroxypropylcellulose to polyethylene oxide with vitamin E TPGS as an additive ($n = 4$)

(From Ref. 12.)

form design and reducing the preparation cost, due to the elimination of the adhesive layer in the system. It is desirable for the film to have adequate adhesion strength so that desirable retention at the application site can be

Fig. 17 Influence of drug loading on the release of chlorpheniramine maleate from matrix tablets using USP method II at 37°C and 100 rpm in 900 ml purified water during the first 6 h: ●, 6% CPM, 94% PEO (1.0 m); □, 12% CPM, 88% PEO (1.0 m); and ▲, 20% CPM, 80% PEO (1.0 m). (From Ref. 12.)

achieved. Bioadhesion, however, has been a difficult phenomenon to measure. The test method itself can be problematic as well as the specific property being measured. Physical-mechanical And bioadhesive characteristics are important parameters in the product development of films, for transdermal, transmucosal, and wound care applications. Repka and McGinity conducted bioadhesion testing of hot-melt extruded HPC films, with various additives in human subjects, utilizing a Chatillon testing apparatus (17, 22). Fig. 18 shows a schematic of the equipment used for this testing. Also illustrated is an example of a force deflection profile obtained from bioadhesion experiments in this study (Fig. 19). These researchers found that the force of adhesion, elongation at adhesive failure, and modulus of adhesion are a function of the type of additive in the extruded film. Fig. 20 shows the force of adhesion of the hot-melt extruded films tested. It can be seen that the force of adhesion was highest for the films containing carbomer 971P (Carbopol® 971P) and a polycarbophil (Noveon AA-1®). This study demonstrates that a single layer HPC film may be produced with the bioadhesive incorporated into the matrix, thus eliminating a separate “adhesive layer” and simplifying the process of transdermal and transmucosal delivery systems.

Miyagawa, Sato, and coworkers studied the controlled-release and mechanism of release of diclofenac in studies conducted in 1996 and 1997 (13, 14). These researchers utilized a twin-screw compounding extruder to prepare wax matrix granules composed of carnauba wax, the model drug, and other rate controlling agents. Their first investigation showed that a wax matrix with high mechanical strength could be obtained even at temperatures lower than the melting point of the wax. Dissolution release profiles of diclofenac from the wax matrix granules were strongly influenced by the formulation of the

Fig. 18 Schematic of the Chatillon apparatus used to perform butt bioadhesion experiments in vivo in human subjects. (From Ref. 22.)

Fig. 19 Example of a force-deflection profile obtained from a butt bioadhesion experiment utilizing hot-melt extruded films in vivo using a Chatillon digital force gauge attached to a motorized test stand. (From Ref. 22.)

granules. The rate-controlling additives that were varied in the formulations included hydroxypropylcellulose, methacrylic acid copolymer (Eudragit L-100), and sodium chloride. The authors emphasized the advantages of using the twin-screw extruder for wax matrix tablets, such as the utilization of low temperatures, high kneading and dispersing ability, and low residence time of materials in the extruder. The investigators concluded in the second study (14) that the selection of rate-controlling agents based on their physicochemical properties, i.e., solubility and swelling characteristics, had a significant impact on the properties of wax matrix granules prepared from this extrusion process.

Koleng and McGinity (44) utilized hot-melt extrusion technology for the preparation of rapid release granules. In this investigation, a hot-melt extrusion process was used to granulate acetaminophen and filler excipients with low molecular weight poly(ethylene glycol)s. The resultant granules were then combined with additional excipients (disintegrant and lubricant) and compressed into tablet

Fig. 20 Force of adhesion of hydroxypropylcellulose hot-melt extruded films containing various polymer additives (12 subjects, $n = 6$). (From Ref. 17.)

compacts. Table 8 lists the release characteristics of the bulk granules and tablets produced from hot-melt extruded granules for formulations containing 15–25% polyethylene glycol 6000. The granules displayed improved drug release compared to the tablets. Tablets containing 15% poly(ethylene glycol) released greater than 80% of the incorporated acetaminophen after 30 min, as required for acetaminophen tablets in the USP 23.

SUMMARY

Although a relatively new technology in the pharmaceutical industry, hot-melt extrusion has been visualized and employed to revolutionize the production of many different dosage forms and systems. It has demonstrated to be applicable to immediate release and sustained release dosage forms including granules, pellets, and tablets. It has

Table 8 Release of acetaminophen from hot-melt extruded granules and tablets prepared from hot-melt extruded granules containing poly(ethylene glycol) 6000 as a thermal binder in 900 ml of 50 mM phosphate buffer (pH 5.8) at 37°C and a paddle speed of 50 rpm

Time (min)	15% PEG 6000		20% PEG 6000		25% PEG 6000	
	Granules (%)	Tablets (%)	Granules (%)	Tablets (%)	Granules (%)	Tablets (%)
5	85.0	18.1	77.1	15.5	79.3	17.4
15	95.5	53.0	99.0	45.3	94.2	35.8
30	98.5	91.4	100.0	77.7	100.0	65.5

60	100.0	100.0	—	100.0	—	97.8

also been shown to provide numerous advantages in the production of thin films for both drug delivery and wound care applications. New chemical entities that demonstrate a low bioavailability due to solubility issues are prime candidates for hot-melt technologies. These drugs and pharmaceutical devices encompass both prescription products and over-the-counter medications. Hot-melt extrusion technologies may offer numerous advantages over traditional methods. Shorter and more efficient processing times to the final product, environmental advantages due to elimination of solvents in processing (including the possibility of recycling), and increased efficiency of drug delivery to the patient make hot-melt extrusion an exciting challenge for the pharmaceutical scientist.

HOMOGENIZATION AND HOMOGENIZERS

Venkatesh Naini

Barr Laboratories, Inc., Pomona, New York, U.S.A.

Shailesh K. Singh

Wyeth-Ayerst Research, Peral River, New York, U.S.A.

INTRODUCTION

Homogenization encompasses techniques of emulsification of one liquid into another, dispersing solid particles uniformly in a product, and disrupting cell membranes. Traditionally, homogenizers have been used in the pharmaceutical industry for emulsification. However, they are finding increasing applications in the manufacture of liposomes (1), nanosuspensions (2), solid-lipid nanoparticles (3), tablet coating dispersions (4), micro-encapsulation (5), and in cell disruption for harvesting therapeutic proteins in cell cultures (6).

Pharmaceutical emulsions are generally classified as oil-in-water (o/w) or water-in-oil (w/o) systems, where the first component represents the dispersed phase, although more complex systems are feasible. The first step in the process of emulsification involves application of mechanical energy (homogenization) to break up the dispersed phase and form a stable emulsion. Homogenization is also used for particle size reduction in pharmaceutical suspensions. Important factors controlling the formation of pharmaceutical emulsions and dispersions are mechanical and/or formulation related. Mechanical forces during homogenization cause droplet or particle size reduction by shear, turbulence, impact, and cavitation (7). Shear is caused by elongation and subsequent breakup of droplets, due to acceleration of a liquid. Cavitation is caused by an intense pressure drop, leading to formation of vapor bubbles in the liquid, which implode causing shock waves in the fluid. This leads to disruption of droplets, particles, and cell membranes. Homogenizers, available from different manufacturers operate using a combination of these forces (8).

This review will focus on commonly used homogenizers in the pharmaceutical industry viz. high-pressure homogenizer, rotor-stator homogenizer, microfluidizer, and ultrasonic homogenizer.

HIGH-PRESSURE HOMOGENIZATION

Auguste Gaulin introduced the first high-pressure homogenizer in 1900 for homogenizing milk (9). The basic high-pressure homogenizer consists of a positive displacement pump attached to a homogenizing valve assembly (Fig. 1). The pump forces liquid into the valve area at a high pressure. As the product is forced through the adjustable gap (D), its velocity increases tremendously with a corresponding decrease in pressure. The emerging product then impinges on the impact ring (C). This sudden change in energy causes increased turbulence, shear, and/or cavitation, resulting in droplet size reduction and uniform dispersion of particles. High-pressure homogenizers are used in emulsification (10–12), preparation of microparticles and nanodispersions (13–16), liposomes (1, 17, 18), and in cell disruption (6, 19). A laboratory scale model of the high-pressure homogenizer is shown in Fig. 2. For emulsion processing a single-stage or two-stage valve assembly can be used, where 10% of the total pressure is applied at the second stage. Another commonly used approach is the multiple-pass homogenization, if a very narrow particle size distribution is needed. This can be achieved by using a series of homogenizers or processing several discrete passes through the same machine.

Several factors affect the final emulsion formulation obtained using high-pressure homogenization. More importantly the level and type of surfactant (11, 12), level of the oily phase, and homogenization process parameters, such as pressure, number of cycles, or discrete passes through the homogenizer, play a significant role. Pandolfe studied the effect of several of these factors and found that the premix condition (prior to homogenization), emulsifier concentration, and energy input by the homogenizer, significantly affected the quality of the final emulsion (11). The effect of increasing homogenizing pressure on emulsions with

Fig. 1 Homogenizing valve assembly in a high-pressure homogenizer. (With permission: APV Homogenizer Group, Wilmington, MA.)

different levels of oily phase, in poor premix (turbine stirrer at 1000 rpm) and good premix (prehomogenized at 500 psi) samples, is shown in Fig. 3. Although droplet size reduction is seen at all conditions, more effective

Fig. 2 Laboratory scale model of a Gaulin type high-pressure homogenizer. (With permission: APV Homogenizer Group, Wilmington, MA.)

Fig. 3 Mean droplet diameter versus homogenizer pressure for emulsions with 1% emulsifier and 5%, 10%, or 20% oily phase. (Adapted from Ref. 11.)

formulations can be obtained by using the lowest amount of oily phase at the highest homogenization pressure with a properly premixed dispersion. It was also concluded that increasing homogenization pressure could effectively reduce the amount of emulsifier required in a formulation. Because of its efficient droplet size reduction, high-pressure homogenization can be used for preparing parenteral fat emulsions (10). Here the requirement is that number of droplets or particles above 1 μm should be limited and no particle should be larger than 5 μm .

Calvor and Muller (13) used high-pressure homogenization and a novel method to prepare biodegradable microparticles of poly(D,L-lactide) (PLA) and poly(D,L-lactide-co-glycolide) (PLGA). They heated the drug-polymer-containing suspensions above the glass transition temperature (T_g) of the polymer, followed by high-pressure homogenization. Above the T_g of the

Fig. 4 Volume size distribution of poly(D,L-lactide-co-glycolide) particles at a homogenization temperature of 75°C (▼), 78°C (■), 79°C (◆) and 80°C (●). (Adapted from Ref. 13.)

polymer, the viscosity of the dispersed phase was lowered leading to efficient droplet size reduction by homogenization. Fig. 4 shows the effect of homogenization temperature on particle size reduction in PLGA ($T_g \sim 40^\circ\text{C}$) containing systems. Traditionally, Gaulin-type homogenizers are known to uniformly disperse and breakup particle agglomerates. Actual breakup of primary particles in the suspension was considered highly unlikely. However, more recently, high-pressure homogenization was successfully employed to prepare nanosuspensions of poorly soluble drugs, starting from micron-sized material (14). Some factors controlling size reduction of drug particles during homogenization include, gap width in the homogenizer, particle shape and size in the feed material, and fragility of drug crystals. Nanosuspensions have promising applications in injectable formulations of poorly soluble drugs or reformulating solution parenterals, which contain toxicologically less favorable excipients. They can also be used to enhance saturation solubility and bioadhesive properties of drugs in the GIT, leading to better bioavailability following oral administration (2). Due to the abrasive nature of suspended drug particles, erosion of contact surfaces and heavy-metal contamination is a major concern during high-pressure homogenization. A study by Krause and coworkers

found that heavy-metal contamination was minimal (<1 ppm) in nanosuspensions after being homogenized at 1500 bar for 50 cycles (20).

Liposomes are phospholipid vesicles containing an aqueous compartment surrounded by one or more bilayers (1). They are finding increasing application as carriers for small molecule drugs, controlled release and targeting of protein and peptide therapeutics, and as immunological adjuvants in vaccines (17). Due to the realization that liposomes need to be produced on a large-scale, high-pressure homogenizers are well suited for industrial production under aseptic conditions. The effects of shear and cavitation during homogenization usually form small unilamellar vesicles (SUVs). The number of passages through the homogenizer and pressure used affects the vesicle sizes (17, 18). For a certain combination of lipid and water, increasing homogenization pressure produces smaller and narrower (decreasing polydispersity) vesicles with an optimum diameter. Any further increase in the number of passes results in broader size distributions due to coalescence (17). Bachmann and coworkers, used a continuously operating high-pressure homogenizer to scale-up production of liposomes using the “one-step” method, where SUVs are prepared from powdered lipid and aqueous drug solution (18). Encapsulation efficiency and entrapped aqueous volume of the vesicles are

Table 1 Encapsulation efficiency and entrapped volumes of vesicles prepared using a high-pressure homogenizer

Number of cycles	40 MPa		Homogenizing pressure (70 MPa)	
	Encapsulation efficiency (%)	Aqueous volume entrapped (l/mol)	Encapsulation efficiency (%)	Aqueous volume entrapped (l/mol)
1	11.8	0.91	11.6	0.89
5	10.4	0.80	9.0	0.69
10	8.0	0.62	7.5	0.58
20	7.6	0.58	6.1	0.47

(From Ref. 18.)

summarized in Table 1. Liposomes prepared with phosphatidylcholine fraction of soybean lecithin (SPC) were homogenized at 40 MPa or 70 MPa, with the higher pressure producing much smaller vesicles. However, extensive recirculation decreased these differences after several passes through the homogenizer. In addition, encapsulation efficiencies decreased at higher pressures and repetitive processing (Table 1).

Recent advances in biotechnology have produced several new protein drugs from mammalian and bacterial cell cultures. High-pressure homogenization is widely used to harvest intracellular proteins and enzymes of interest in cell cultures (6, 19). Lander et al. conducted a mechanistic study of cell disruption caused by homogenization (19). Shear and cavitation were found to play an important role in cell membrane disruption and release of intracellular contents. High-pressure homogenizers for cell disruption applications use special valve assemblies for efficient rupture of cell walls (6). Other process parameters to consider during cell disruption are viscosity of the cell suspension, flow rate, and number of passes through the homogenizer.

MICROFLUIDIZATION

The microfluidizer is a high-pressure homogenizer that works, on a different principle. The pre-homogenized liquid is forced through an interaction chamber using a high-pressure pump. The interaction chamber consists of ceramic microchannels, which cause the liquid feed to split into two streams. These streams are then recombined at very high velocities producing forces of shear, impact, and cavitation, which cause droplet or particle-size reduction in emulsions and suspensions. A complete

description of the operation of the microfluidizer is summarized in US Patent 4,533,254 (21). A schematic diagram of the microfluidizer process is shown in Fig. 5. These homogenizers are commercially available from Microfluidics Corporation (Newton, MA). Microfluidizers are capable of handling emulsions (21–23), artificial blood (24, 25), suspensions (26), and liposomes (27–30). A microfluidizer that can operate at process pressures of up to 40,000 psi is shown in Fig. 6.

Because of their efficient droplet size reduction and ease of scale-up, microfluidizers are frequently used to prepare parenteral feeding emulsions (22, 23). Droplet diameters were directly related to the process pressure used, number of passes through the microfluidizer, and concentrations of emulsifier and oily phase in the emulsion (22). Reduction in droplet size of a 10% emulsion as a function of number of passes through the microfluidizer is shown in Fig. 7 (22). When the homogenizer was operated at its maximum operating pressure of 10,000 psi, droplet diameters decreased from 380 nm for a single pass to a plateau of 250 nm after four cycles, with further processing having no significant effect. Lidgate et al. used a microfluidizer to prepare an o/w parenteral emulsion for use as a vaccine adjuvant and compared its stability to emulsions prepared by other methods (23). Stress tests to induce creaming were used to test emulsions produced by various techniques. Microfluidization produced a superior parenteral emulsion compared to a homogenizer mixer. Stability correlated well with increasing number of microfluidizer cycles used to process the emulsion (23).

The microfluidizer has distinct advantages over conventional milling processes in particle size reduction of pharmaceutical suspensions. Absence of heavy-metal contaminants due to surface erosion and easy scale-up to production were observed when using the microfluidizer

Fig. 5 Microfluidizer processor flow diagram. (Microfluidics Corporation, Newton, MA.)

for preparing radiopaque suspensions (25). Several reports deal with scaled up production of liposomes using the microfluidizer (28–30). In one study, liposome dispersions with relatively high lipid concentrations (400 $\mu\text{mol/ml}$) could be processed to narrow size

distributions using the microfluidizer (26). In addition, a US Patent (4,776,991) describes the large-scale production of liposome encapsulated hemoglobin for use as a blood substitute (30). Liposomes produced with high-pressure homogenizers usually result in small unilamellar vesicles (SUVs). Their main disadvantages are low encapsulation efficiency and tendency to leak their contents more often than multilamellar vesicles (MLVs). Sorgi and Huang used the microfluidizer to prepare cationic liposomes, where the active component is not encapsulated, but forms

a complex with the liposome using charge interaction (29). The microfluidizer was well suited for preparation and scale-up of cationic liposomes of a plasmid DNA, which was successfully used in gene therapy clinical trials (29).

ROTOR-STATOR HOMOGENIZATION

The rotor-stator homogenizer is one of the most commonly used pieces of equipment in the pharmaceutical industry. Although they have limited capability in achieving very fine droplets or particles, rotor-stator mixers are capable of handling liquids at much higher viscosities, compared to high-pressure homogenizer and the microfluidizer. A rotor-stator homogenizer consists of an impeller in close tolerance to a stationary housing, which restricts the flow of liquid caused by the impeller movement. Shear and impact comminute particles and droplets caught between the rotor and stator (5, 31). The colloid mill is an extreme example of the rotor-stator homogenizer, where the gap between the rotating truncated cone (rotor) and its housing (stator) is adjustable. However, the colloid mill suffers from disadvantages like generation of excessive heat and incorporation of air in the finished product. Various geometries and configurations of the mixing head in the rotor/stator design are available from different manufacturers (8). They can be used in the batch mode and continuous, or "in-line," mode. An "in-line" rotor/stator homogenizer is depicted in Fig. 8. Parameters affecting final product quality in rotor/stator homogenization are homogenization intensity, residence time of product in the shearing field, viscosity of the dispersed and continuous phases, surfactant concentration, rotor/stator design,

Fig. 8 An in-line rotor/stator homogenizer. (IKA Works, Wilmington, NC.)

volume of the mixer, and volume ratio of the two phases (5, 31).

Djakovic and coworkers, studied several factors such as homogenization time, emulsifier concentration, and homogenization intensity to determine optimal parameters for emulsification, using a rotor-stator homogenizer (32). Mean droplet diameter and polydispersity were used as measures of final product quality. For constant homogenization intensity (rpm) and mixing time, droplet size and polydispersity decreased with increasing emulsifier concentration before reaching an optimum level (32). Maa and Hsu (5) compared the batch mode and a flow-through apparatus, using rotor/stator homogenization for microencapsulation. Emulsion droplets obtained using the flow-through method were consistently higher than the batch mode. Since emulsification is effected by residence time of liquid in the shearing field, the flow-through method induced lower shear compared to the batch mode. However, using effective recirculation in the flow-through mode can overcome this problem (31).

ULTRASONIC HOMOGENIZATION

Sonication emulsifies primarily by cavitation. An ultrasonic homogenizer consists of a generator, converter, and horn tip (8, 31). The converter consists of a piezoelectric quartz crystal, which transforms electrical energy into high intensity vibrations and transmits them to the horn tip immersed in the liquid. Droplet size reduction occurs

Fig. 9 Effect of sonication time on emulsion droplet size for 0.4 g/ml of poly(methyl methacrylate)/methylene chloride solution in 6% of polyvinyl alcohol (PVA) solution at a volume ratio of 15:2 (ml/ml) sonicated at 20% (○), 50% (□), and 100% (●) of full power. (Adapted from Ref. 31.)

Table 2 List of homogenization equipment supplied by various manufacturers

Type of homogenizer	Model (manufacturer)	Mode of operation (Batch/continuous)	Operating parameters	Capacity	Applications
High-pressure	APV Model 2000 (APV Homogenizers)	Laboratory scale; batch or continuous	Maximum pressure: 30000 psi	Batch (100 ml) Continuous (11 L/h)	Emulsions, nanodispersions, liposomes, ointments, cell disruption, vaccines, parenteral emulsions
	Gaulin and Rannie Models (APV Homogenizers)	Production scale; batch or continuous	Maximum pressure: 21750 psi	Up to 50000 L/h	
	Ariete Model NS8315 (Niro Soavi)	Production scale; batch or continuous	Pressure range: 2000–15000 psi	8000–50000 L/h	
	M-110Y (Microfluidics)	Laboratory scale; batch or continuous	Pressure range: 3000–23000 psi	Batch (>60 ml) Continuous (250–600 ml/min)	Dispersions, emulsions, cell disruption, encapsulation, liposomes, vaccines, parenteral emulsions
Microfluidizer	M-140K (Microfluidics)	Laboratory scale; batch or continuous	Pressure range: 8000–40,000 psi	Batch (1000 ml) Continuous (500 ml/min)	
	M-210EH (Microfluidics)	Production scale; batch or continuous	Pressure range: 2500–30,000 psi	Batch (3.8 L) Continuous (5.7 L/min)	
	Silverson Model GX25	Production scale; batch	Maximum rpm: 3600	2400 L (low viscosity) 400 L (high viscosity)	Emulsions dispersions, pastes, creams, lotions
	Ultra-Turrax UTL (IKA Works, Inc.)	Production scale; continuous	Maximum rpm: 6000	3500 L/h	
Ultrasonic	Microson XL2007 (Misonix, Inc.)	Laboratory scale; batch	Power: 100 W; Frequency: 22.5 kHz	<50 ml	Emulsions, dispersions, cell disruption
	Floccell 800D (Misonix, Inc.)	Production scale; continuous	Power: 475 W; Frequency: 20 kHz	With booster horn 40 L/min	

mainly by intense shock waves generated in close proximity to the tip. For large-scale applications, ultrasonic homogenizers can be used in the continuous mode with a flow-cell (33). In general, droplet size reduction in ultrasonic homogenizers is affected by sonication intensity, viscosity of the mixture, emulsifier concentration, and time of sonication (31, 34). Fig. 9 shows the effect of increasing sonication power on emulsion droplet size in liquid-liquid emulsification (31). Higher sonicating power resulted in smaller emulsion droplets. At all power levels the droplet size reduced dramatically, initially followed by a leveling-off phase. Sonication is comparable to rotor-stator homogenization if sufficient power is used. However, as liquid viscosity increases, rotor-stator homogenization is more efficient due to shear effects (31).

EQUIPMENT CONSIDERATIONS

A variety of homogenizers capable of performing a range of processes are available. Important considerations during formulation development include the feasibility and availability of pilot and production scale equipment, which can reproduce the same results. A sampling of homogenizers available from selected manufacturers is given in Table 2. High-pressure homogenizers and microfluidizers are available in a wide range of capabilities ranging from bench-top models to production equipment capable of handling large amounts of material. These homogenizers are limited in their handling of high viscosity fluids compared to rotor-stator homogenizers, which are designed to handle even thick pastes and creams. However, particle size reduction is more efficiently carried out using high-pressure homogenizers and microfluidizers. Ultrasonic homogenizers are also capable of handling large volumes by using the continuous or flow-through approach. However higher intensities are needed to cause cavitation and droplet reduction in high viscosity fluids. As indicated in Table 2, high-pressure homogenizers and microfluidizers can be easily adapted for batch or continuous processing. Rotor-stator homogenizers are available either as batch processors or in-line dispersers, which can be used continuously or by recirculating the product.

LENS CARE PRODUCTS

Masood Chowhan

Ralph Stone

Alcon Laboratories, Fort Worth, Texas, U.S.A.

INTRODUCTION

Contact lenses are made of polymeric materials designed and fabricated to correct vision. Because these lenses are removed from the eye after a prescribed wear time, lens care products are required to clean, disinfect and rinse them prior to reinsertion to avoid ocular infections and other complications. Lens care products are also required to enhance the comfort of lens wear.

HISTORICAL OVERVIEW

Lens care products are relatively new compared to many other pharmaceutical products. Leonardo da Vinci was the first to conceive the concept of the contact lens. In 1508 he illustrated the concept of vision involving “upside down” images with a water-filled sphere covering the eye. However, the actual development of contact lenses did not occur until about 100 years ago (1887–1888) when scleral contact lenses were fabricated. The three innovators credited for this are Dr. A.E. Fick, a physician in Zurich, F.A. Mueller, a maker of prosthetic eyes in Germany, and Dr. Eugene Kalt, a French physician. The earlier lenses were made of glass. In the late 1930s (1937–1939), Mullen, Oberg and Gyrrfy are credited with fabricating plastic contact lenses made from methyl methacrylate (PMMA). However, Kevin Tuohy, who filed a patent for contact lens design in 1948, is recognized as the “father” of modern day corneal contact lenses. These early lenses were rigid and uncomfortable with very low oxygen transmission. Advances in rigid lens technology have provided materials capable of oxygen transmission required to maintain corneal health. In the 1960s Otto Victerle developed the hydrophilic soft contact lens from polyhydroxyethyl methacrylate (HEMA). Hydrophilic soft contact lenses are the primary lenses available today. Since then, significant technological advances have been made in contact lens material, designs, and manufacturing processes. In 1990, the estimate of contact lens wearers in the United States alone was around 30 million.

The commercialization of the first pharmaceutical quality lens care products occurred in the 1950s. Harry Hind, a pharmacist and founder of the Barnes-Hind Company, has been credited as one of the first to develop and commercialize a wetting and storage solution for the rigid PMMA plastic lenses. Prior to his efforts, the literature mentions formulation of a saline solution containing sodium bicarbonate to be used with scleral lenses made from glass.

CURRENT CONTACT LENS MATERIALS AND FUTURE DIRECTIONS

Most of the materials currently used in fabricating contact lenses have been available since the mid-1960s with the exception of polymethyl methacrylate. Lens materials can be broadly classified as follows:

Rigid Gas-Permeable Lenses:

- Cellulose acetate butyrate
- Silicone
- Silicone acrylate
- Fluoro silicone acrylate
- *t*-Butylstyrene
- *t*-Butylstyrene-*co*-silicone acrylate

Soft Hydrophilic Lenses:

- Polyhydroxyethyl methacrylate
- Polyhydroxyethyl methacrylate-*co*-methacrylic acid
- Polyglyceryl methacrylate
- Polyhydroxyethyl methacrylate-*co*-polyvinylpyrrolidone
- Polyvinylpyrrolidone-*co*-methyl methacrylate
- Polyhydroxyethyl methacrylate-*co*-silicone (silicone hydrogel)

In addition to these materials, several others, such as polyurethanes, polysulfones, polyvinyl alcohol, and various copolymers, have been tried or are under development. Recently, silicon hydrogel lenses with high oxygen permeability were marketed. The future trends in

material development will continue to include polymers which have a high degree of oxygen permeability, resist accumulation of metabolic products of the cornea, and materials that resist lens deposits and bacterial attachment on lens surfaces to minimize the potential for ocular infection.

Classification of Contact Lenses Currently Marketed

During a period beginning from mid-1970, numerous hydrophilic and rigid gas-permeable lenses were introduced into the market. Although many had similar basic chemical compositions, they contained different additives designed to achieve desirable properties or to avoid infringement of existing patents. Such a proliferation of contact lens materials created confusion regarding Food and Drug Administration (FDA) criteria for approval of contact lenses and their care products. In the mid-1980s, the FDA worked with the contact lens manufacturers and evolved a classification for soft contact lenses based on the ionic or nonionic nature of polymers constituting the lens material and the water content. A classification was also worked out for rigid gas-permeable (RGP) lenses based on the chemical nature of the polymers. It is interesting to note that contact lenses and their care products were originally considered as drugs. However, upon passage of the U.S. Medical Device Act in 1996, contact lenses were reclassified as devices. Contact lenses and their care products were considered Class-III devices, which mandate the filing of a premarket approval application and obtaining FDA approval prior to marketing. Recently these products were reclassified as Class II devices and are currently cleared for marketing under the 510(k) premarket notification section of the regulations.

LENS CARE PRODUCTS BY FUNCTIONAL PURPOSE

Marketed lens care products fall mainly into the following categories: cleaners, disinfectants, lubricants, and multipurpose products. Cleaners are subdivided into daily or weekly cleaners. Disinfectants comprise solutions containing chemical antimicrobial agents, which do not require heating the lenses, and preserved or unpreserved saline solutions, which are used with an electrical thermal device for lens disinfection. These products are also used to rinse contact lenses. Lens lubricants are intended to enhance the comfort of lens wear and are used prior to insertion and during wear. Multipurpose solutions are intended to

accomplish two or more of the functions described earlier (cleaning, rinsing, and disinfection).

Rigid lens care also includes conditioning solutions to make the basic hydrophobic polymers wettable when placed on the eye.

PRODUCTS FOR CLEANING SOFT CONTACT LENSES

Lens Deposits

Composition

Basically there are two types of deposits: those resulting from tear components and those derived from other sources. Tear components especially proteins can accumulate on the lens surface. These proteins can denature or change conformations during absorptions on over tissue. Most deposits, with the exception of those that are tenaciously bound to the lens, can be cleaned easily with a surfactant-type of daily cleaner. Deposits resulting from tear components include proteinaceous deposits such as lysozyme, lactoferrin, albumin, globulins, etc. Proteinaceous deposits are present on all types of lenses. However, the amounts differ, depending on the number of ionic charges on and in the lens, the pore size, and the relative hydrophobicity of the polymers. For example, conventional nonporous and uncharged hard PMMA lenses with a hydrophobic surface attract very little proteinaceous deposits. Among the soft contact lenses with hydrophilic surfaces, the extent of deposits differs among various groups. For example, Group-4 lenses, which exhibit considerable negative charges due to methacrylic acid content, interact readily and heavily with a positively charged protein (lysozyme). Group-2 hydrogel lenses have no ionic charges, but can acquire substantial amounts of protein because of their large pore size. Besides protein deposits, lipid deposits are also found on contact lenses. These deposits are more common with rigid gas-permeable lenses because of their lipophilic nature. Such deposits may include cholesterol esters, wax esters, triglycerides, sterols, fatty acids, etc. Calcium present in tears results in calcium carbonate or phosphate-type of deposits as well as so-called mixed deposits (calcium bonded to organic compounds). Such deposits are common mainly in high water content soft contact lenses and are difficult to remove without damaging the contact lenses. Other deposits result from the patient environment. These include deposits resulting from cosmetics, make-up, and hair-spray, as well as materials from the wearing environment such as pollen dust and debris.

Table 1 Daily cleaners with shearing particles

Trade name	Manufacturer	Type of particle	Used with
OPTI-CLEAN	Alcon	Nylon	Soft, PMMA, RGP
OPTI-CLEAN II	Alcon	Nylon	Soft, PMMA, RGP
OPTI-FREE daily cleaner	Alcon	Nylon	Soft, PMMA, RGP
Boston cleaner	Polymer technology	Silica	PMMA, RGP
Boston advance cleaner	Polymer technology	Silica	PMMA, RGP

Problems associated with lens deposits

Cleaning is one of the most important steps in contact lens care. It helps in the removal of surface debris and contaminating microorganisms, thus facilitating the disinfection process. Improperly cleaned lenses can cause discomfort, red eye, decrease in visual acuity, and giant papillary conjunctivitis (GPC). The last often requires discontinuance of lens wear, at least until the symptoms clear. The change from heat to cold disinfection technology and the introduction of disposable lenses may have reduced the incidence of GPC. However, since these lenses can be worn on an extended basis for up to seven days without cleaning, GPC can still occur, as has been noted in the literature.

Classification of Lens Cleaners

Daily cleaners versus weekly cleaners

Daily cleaners generally contain surfactants and are used every day. They may also contain abrasive (deposit-shearing) particles, which enhance product performance. Commonly used daily cleaners with deposit shearing particles are listed in Table 1.

There are two types of weekly cleaners: those containing enzymes and those containing concentrated surfactants. Products containing enzymes for daily use are usually accepted by the patients and recommended by practitioners. Commonly used enzymatic products are listed in Table 2.

In-the-eye versus out-of-the-eye cleaners

Most of the cleaners marketed are out-of-the-eye cleaners; however, in recent years there has been a trend to try to develop cleaners for use while the lenses are inserted. A specific instance where such products could be beneficial is the case of the extended-wear lenses, which are not removed daily but are worn up to a week at a time. Generally, these cleaners are less effective in removing deposits already formed on the lens surface. However, they may play a role in retarding deposit formation.

Consumer versus professional use cleaners

Cleaners for lens wearers are used either on a daily or weekly basis and are fairly innocuous. Even upon gross misuse, they are not likely to be sight-threatening. Professional cleaners, however, are potent as well as toxic if not used properly. They are also more likely to damage the lens if used too frequently.

Active Components of Lens Cleaners

Surfactants

Surfactants are broadly classified into nonionic, anionic, cationic, and amphoteric types. Nonionic and amphoteric surfactants are most commonly used in contact lens cleaners, because strong anionic surfactants are generally toxic to the cornea. The recommended procedure by the manufacturer removes several types of deposits, except the most tenaciously bound and denatured proteins, lipids, and mucins. Surfactant-type cleaners are also effective in removing greater than 99.9% of microorganisms contaminating the lens. There are several mechanisms for their effectiveness, which include displacement of contaminants from the surface by mechanical force after the surface debris has been loosened as a result of a reduction in the interfacial tension. In addition, surfactants act by emulsification and micellar solubilization. They may also play a role in preventing or retarding deposition of contaminants.

Enzymes

Enzymes are biochemical molecules responsible for catalyzing reactions in which certain chemical bonds are broken. Their mechanism of action in cleaning involves attacking substrate protein, lipid, and mucin deposits, and fragmenting them into smaller molecules which are readily removed by the mechanical action of rubbing with the fingers and rinsing. Marketed products contain different enzymes, such as papain, pancreatin, and subtilisin. Papain and subtilisin are only proteolytic in nature, whereas pancreatin is a broad-spectrum enzyme

Table 2 Enzymatic products for contact lenses

Trade name	Manufacturers	Enzyme	Source	Dosage form
OPTI-FREE enzymatic cleaner	Alcon	Pancreatin	Mammals	Tablet
OPTI-ZYME enzymatic cleaner	Alcon	Pancreatin	Mammals	Tablet
SupraClens daily protein remover	Alcon	Pancreatin	Mammals	Liquid
Allergan enzymatic contact lens cleaner	Allergan	Papain	Plant	Tablet
ProFree/GP weekly enzymatic cleaner	Allergan	Papain	Plant	Tablet
Ultrazyme enzymatic cleaner	Allergan	Subtilisin-A	Microrganisms	Tablet
ReNu effervescent enzymatic cleaner	Bausch & Lomb	Subtilisin	Microrganisms	Tablet
ReNu thermal enzymatic cleaner	Bausch & Lomb	Subtilisin	Microrganisms	Tablet
Sensitive eyes enzymatic cleaner	Bausch & Lomb	Subtilisin	Microrganisms	Tablet

containing protease, lipase, and amylase enzymes that digest proteins, lipids, and mucins. Enzyme cleaners are effective in attacking all lens proteins, including the removal of tenaciously bound and denatured deposits, that cannot be removed by surfactant cleaners. Traditional enzymatic cleaning of contact lenses is recommended usually once a week. The soaking time varies from 15 min to overnight, followed by a disinfection process. However, more recently products have been introduced that can be used simultaneously during disinfection on a daily process. Certain enzyme products are recommended for this single-step cleaning and disinfection, using a heat or chemical regimen that enhances convenience and increases user compliance.

Oxidizing agents

Oxidizing agents such as sodium perborate and sodium percarbonate have also been used in cleaning contact lenses. None of these products are currently marketed for that purpose in the United States. Products marketed earlier were withdrawn because of their deleterious effects on lens polymers.

Deposit-shearing particles

Deposit-shearing particles are incorporated in suspension form in some daily cleaners. These formulations are more effective than daily surfactant cleaners as they are capable of removing tenaciously bound and denatured deposits. Some of the marketed products contain polymeric beads or silica. When used as recommended, these products are very effective and do not scratch the lens surface.

Chelating agents

Chelating agents such as disodium edetate (EDTA) are commonly used in lens care products to enhance the antimicrobial activity of preservatives and remove calcium and magnesium from the lens. EDTA is the most effective

chelating agent known for calcium and magnesium. Other chelating agents have been used such as phosphonates, which are most effective against iron.

Solvents

Solvents such as isopropyl alcohol have been incorporated in daily cleaners to aid in removing lipid type of deposits. Such solvents have been reported to affect certain lens materials, especially silicone acrylate rigid gas-permeable lenses.

Accessory Cleaning Products

Hand soaps

In the daily care of contact lenses, wearers are instructed to clean their hands with soap and to dry hands their hands with lint-free towels prior to handling their lenses. Selection of the specific soap product is important. In addition, to cleaning the hands thoroughly, it should be rinsing and should not cause ocular irritation even if residual amounts are transferred to the lens. With these considerations in mind, some hand soaps have, therefore, been designed specifically for contact lens users.

Cleaning devices

The general method of daily lens cleaning involves rubbing lenses between the index finger and thumb or placing the lens in the palm of the hand and rubbing with the index finger after applying cleaning solution to the surface. However, there are also special devices available in the market for cleaning lenses. They are said to clean lenses more effectively and avoid potential scratching by the fingers. These devices involve mechanical agitation and are manually or electrically operated. Ultrasound devices have been used mainly by lens practitioners in their office. None of those devices per se are effective in removing tenaciously bound, denatured deposits.

PRODUCTS FOR DISINFECTING CONTACT LENSES

Disinfection of contact lenses is an important step in preventing ocular irritation, red eye, and potential loss of eyesight due to corneal ulcers resulting especially from *Pseudomonas aeruginosa* infections. The pore openings of hydrophilic soft contact lenses are estimated to be between 3.0 and 7.0 nm, and are considerably smaller than the average bacterial particle size of 0.2–1.0 μm or fungus particle size of 2–6 μm . Even viruses ranging in particle size from 25 to 200 nm are large in size compared to the pore openings of soft lenses. None of the microorganisms can penetrate an intact lens matrix. However, when lenses are not properly cared for, some fungus growth facilitates the penetration of fungal hyphae into the matrix.

Contact lenses and their cases are frequently contaminated by microbes. Although studies have indicated that as many as 30% of lens cases are contaminated, the incidence of permanent ocular damage due to this is very low. Nevertheless, it is critical to properly instruct lens wearers and emphasize the importance of disinfection in order to avoid the potential risk of ocular infection or damage to the eyesight.

Thermal Versus Chemical Disinfection

Both thermal and chemical methods are commonly used for the disinfection of soft contact lenses. With the former, a case containing the lenses immersed in saline solution is heated by an electrical unit with a predesigned heating cycle. The current FDA requirement for thermal disinfection by saline solution requires a minimum temperature of 80°C for 10 min within the contact lens case. This ensures elimination of vegetative forms of ocular pathogens but not the spores.

The chemical method involves antimicrobial compounds with an adequate antimicrobial spectrum and biocidal action. The FDA guidelines include the methods for determination of efficacy for all disinfecting solutions. The initial testing process is defined as the elimination or reduction of microorganisms achieved over the disinfection period. The FDA guidelines also provide a method for manufacturers to conduct use tests on purposely contaminated contact lenses, following a complete disinfection regimen, which includes cleaning and rinsing. This test is generally known as the FDA regimen test. The FDA guidelines specify the types and levels of organisms as well as the details of the test. Other methods using ultraviolet light, microwave, and ultrasonics, have been

tried for lens disinfection but are not widely applied because of ineffectiveness or deleterious effects on lens materials.

The advantage of the thermal method is that it ensures complete elimination of vegetative forms of microorganisms, whereas chemical disinfectants may encounter some resistant organisms. Although the thermal method is preferable from the microbiological viewpoint, it has several disadvantages: It is a complex method involving the use of electrical devices. The failure of an electrical heating unit to perform properly presents a potential risk of ocular infection. Malfunctioning units and improper use may result in electrical shock to users and fires have been reported. If the saline solution in the lens container evaporates during the heating cycle as a result of carelessness in not properly tightening the lens case cap, the lens might be damaged. Thermal disinfection has been cited in shortening lens life and enhancing the formation of deposits on the surface. This occurs especially if the lens has not been properly cleaned prior to thermal disinfection. The method is not practical for campers who are frequently without an electrical outlet.

Chemical disinfection, on the other hand, is not as effective in killing organisms as thermal disinfection, but has several advantages: It is simple to use, thereby ensuring greater user compliance. Lens life is longer with chemical disinfection as lenses are not subjected to daily heat treatment. The method results in fewer deposit problems as surface debris left on the lens surface due to improper cleaning is not baked by heat.

The choice between thermal and chemical disinfection depends, to a large extent, on the recommendation of the lens practitioners. Factors involved include the wearer's sensitivity to preservatives, needs, personal hygiene habits, and product cost. Today fewer heat disinfection units are available.

Thermal Disinfection

Soft contact lenses were introduced in the United States in 1972. At that time, the thermal disinfection method was the only method available. It uses either preserved or unpreserved saline solution.

Unpreserved versus preserved saline solutions

Prior to the commercial availability of pharmaceutically prepared saline solutions, they were prepared by the lens wearer using salt tablets and distilled water. This method was undesirable and created many problems as the pH and osmolarity of such solutions were not controlled, which often resulted in parameter changes in some soft lenses. The major problem stemmed from noncompliance.

In order to reduce cost, tap water was often used instead of distilled water for preparing saline solutions, which resulted in mineral deposits on the lens surface. Microorganisms proliferated in nonsterile saline solution prepared with distilled water stored for a number of days and instilled in eyes directly to hydrate contact lenses while they were worn. Such gross misuses resulted in ocular infection affecting vision. By the mid-1980s products label and package inserts warned against the use of tap water for contact lens care. In the mid-1970s, pharmaceutically prepared sterile saline solution preserved with thimerosal was introduced to eliminate the disadvantages of home-made saline. However, thimerosal often caused a brownish and grayish lens discoloration and also led to red-eye and sensitization reactions in some patients. Soon after the introduction of pharmaceutically prepared preserved saline solutions, most salt tablets were withdrawn from the market. They were, however, reintroduced because of the red-eye and sensitization problems associated with thimerosal-preserved salines. In 1987, the FDA asked companies marketing salt tables for their voluntary withdrawal because of several incidences of keratitis caused by *Acanthamoeba* species, resulting in significant loss of vision or eyesight of several lens wearers. Most of these cases were associated with the use of salt tablets to prepare home-made saline solution.

In the United States today saline solutions are marketed in preserved and unpreserved forms; both are sterile and pharmaceutically prepared. The unpreserved solutions are available in unit dose or multidose plastic containers and multidose aerosols. In the latter instance, the pressurized container and the construction of the valve prevents inoculation of microorganisms into the container during its use, thus maintaining sterility more effectively in comparison to multidose nonpreserved saline solution in plastic containers. Nonpreserved saline solution in an aerosol container is, therefore, preferred over nonpreserved saline solution because it eliminates the potential of irritation and sensitization reactions caused by thimerosal and sorbic acid preserved salines. Such reactions may result in considerable patient discomfort and require temporary discontinuance of lens wear. However, the newer preservatives Polyquad and Dymed do not cause significant levels of such reactions. The disadvantage of unpreserved saline solution in unit dose is higher cost. There is also a potential risk of ocular infection as it is a common practice among lens wearers to leave their lenses in a lens case containing an unpreserved saline for several weeks, often without appropriate disinfection. Unpreserved saline does not protect against proliferation of microorganisms.

In contrast, preserved saline helps to prevent microbial growth when lenses are not worn and stored in lens cases. They are also less costly in comparison to unit dose or multidose pressurized nonpreserved saline solution containers. As already noted, the principal disadvantage of preserved saline solution is that some of the preservatives, such as thimerosal and sorbic acid, have the potential of causing irritation and sensitization in some patients. However, these reactions are not sight-threatening. In most instances these symptoms clear on discontinuance of the product without requiring any drug therapy. Again, this problem now appears to have been eliminated or greatly minimized with the introduction of newer preservatives such as Polyquad and Dymed.

Both preserved and unpreserved saline solutions are multifunctional solutions. In addition to thermal disinfection, they are also used to dissolve enzyme tablets in cleaning contact lenses, as a rinsing solution following cleaning and chemical disinfection, and as a lens storage solution.

Thermal disinfecting units

The FDA guidelines require that thermal disinfecting units must attain a minimum temperature of 80°C for 10 min in the saline solution, which is placed in the lens cases. There are several units on the market, which meet these requirements; they vary in their time-temperature profiles. Certain lenses such as those belonging to the FDA Group-4 classification (ionic, high-water-content lenses) do not withstand repeated heat treatment and tend to discolor. In general, FDA Group-4 lenses are not heat disinfected. Units on the market today have a thermostat, which cuts off the electrical current when a certain temperature is reached, eliminating the need for patients to switch it off. However, malfunctioning of units occasionally does occur.

Units on the market today are much different from those available earlier. The first unit was analogous to a "baby bottle warmer." Lenses were placed in a lens case, which was placed in a reservoir of water in an electrical heating unit. The temperature in the reservoir reached almost the boiling point of water and the time for disinfection was 30 min. To ensure not only disinfection but also sterilization of lenses, a unit was introduced capable of achieving 120°C for 20 min to ensure complete elimination of vegetative organisms as well as spores. This unit, however, was not successful since the high temperature was detrimental to many lens polymers. The current trend is toward developing a heating unit, which reaches temperatures below 80°C but ensures elimination of vegetative forms of ocular pathogens.

Chemical Disinfecting Agents (Oxidizing and Nonoxidizing)

There are two categories of chemical disinfecting solutions: The first category comprises those containing nonoxidizing chemical antimicrobial agents, which are nontoxic at the concentration level used in the products. The second category constitutes those containing oxidizing agents, which are toxic at the level used for disinfection but are degraded to a nontoxic level during the disinfection process over a course of time or by use of a second step that involves a neutralizing ingredient. Disinfecting solutions containing oxidizing agents (specifically hydrogen peroxide) gained popularity among lens practitioners in the mid- to late-1980s because of the absence of traditional preservatives, which often caused red eye and delayed hypersensitivity. However, the neutralizing solution used with hydrogen peroxide often contains preservatives that can cause ocular reactions. Lens practitioners liked the concept of hydrogen peroxide decomposing to innocuous water and oxygen. Fewer reactions have been observed with such products, but the long term toxic effects on the eye of the free radicals which are generated by low concentrations of undergraded oxidizing agents are not well known. Hydrogen peroxide products can cause severe toxic reactions if the products are not used properly and the patient inserts a lens without neutralizing the hydrogen peroxide.

The ideal chemical disinfecting agent should possess the following properties: It should have excellent wearer's acceptance in terms of being nonirritating, nonsensitizing, and easy to use. It should be relatively nontoxic compared to the earlier preservatives in terms of cytotoxicity, including its effects on epithelial and endothelial cells as well as its ability to maintain mitotic activity of corneal epithelial cells. It must have an adequate antimicrobial spectrum and be able to eliminate ocular pathogens in short lens-soaking regimens. It should not bind or bind minimally to the lens surface. It should be compatible with the lens and not cause discoloration or alter the tint of colored contact lenses.

A hydrogen peroxide disinfection system for soft lenses was tried initially in the early 1970s. The system failed to gain FDA approval because of the potential toxic nature of the chemical, the complexity of several steps, and the cost. The system was approved by the FDA in the early 1980s after having undergone significant refinements compared to the original system.

All products currently marketed in the United States under the oxidizing agent category contain hydrogen peroxide. In the international market, products containing chlorine-releasing agents are also available. These

products are generally indicated for the disinfection of hydrophilic soft contact lenses and are contraindicated for rigid gas-permeable lenses. Most of the hydrogen peroxide is decomposed by catalytic degradation (platinum ring); chemical neutralization using pyruvate, sodium bisulfite, or sodium thiosulfate; dilution and rinsing; and enzymatic neutralization (catalase).

Hydrogen peroxide, on degradation, forms water and oxygen and, hence, it is perceived by practitioners as a superior product. However, most of the neutralizers used in the second step contain preservatives such as thimerosal and sorbic acid, and stabilizers such as stannates or phosphonates. Consequently, they have the associated disadvantages of those ingredients. On the other hand, not having a preservative in a neutralizer makes these products vulnerable to microbial growth on accidental contamination. A single-step product containing hydrogen peroxide is also available on the market, which is convenient, but has the same disadvantage of not having any preservative effect at the end of the disinfection cycle. The disinfecting time recommended by various companies ranges from 10 min to an overnight soak. This category of disinfecting agents has a better antimicrobial spectrum and a faster kill rate. However, their shortcomings included toxicity if the regimen was not followed properly, complexity of use, and zero to minimal protection against microbial recontamination once the disinfection cycle was complete.

The first generation nonoxidizing chemical disinfection solution contained a combination of antimicrobial agents incorporating thimerosal with chlorhexidine or alkyltriethanol ammonium chloride. These solutions are now not commonly used because of the thimerosal problems as discussed previously. The newer antimicrobial agents, Polyquad and Dymed, because of their molecular structure and large molecule size have a better profile. These antimicrobial agents were introduced in the late 1980s and their long-term use has not caused reactions similar to those observed for older antimicrobial agents. Products with these agents currently dominate the lens care market.

PRODUCTS FOR ENHANCING SOFT CONTACT LENS WEAR COMFORT

Factors Contributing to Wear Comfort

It has already been noted that hydrogel contact lenses are inherently more comfortable than rigid (RGP or PMMA) lenses. This is related to the former's superior flexibility and hydrophilic character which permits incorporation of substantial amounts of water (38–74%) into the lens

material. However, after periods of wear time, some lenses may experience changes in hydration, that may be related to deposits, environmental (e.g., temperature and humidity) changes and improper care. In particular, "dry spots" may become evident on the lens with attendant reduction in comfort and visual acuity. When this happens, the wearer may benefit from periodic administration of rewetting (or soothing or comfort) solutions onto the lens while being worn. These solutions are usually low-viscosity aqueous compositions containing polymers or surfactants, which enhance the wettability of the surface, facilitating the spreading tears, and enhancing the stability of the tear film. They may also provide cushioning and lubricating actions, lessening impact, and reducing the frictional forces of the eyelids as they move across the lens on the corneal surface. The frictional forces would be especially important in instances where deposits or debris on the lens are present in sufficient amounts to cause physical irritation to the ocular tissue. In addition to wetting, cushioning, and lubricating, the ability of the solutions to facilitate removal of contaminants and retard further soilage are also desirable attributes. It is also desirable, in terms of convenience to the lens wearer, that the frequency of administration of drops of the above-mentioned types be minimal. Therefore, the use of polymers and surfactants that associate with the (deposited) lens and resist removal by the rinsing action of the tears is called for (i.e., polymers and surfactants with good substantivity).

Although rewetting efficacy is usually the primary requirement for hydrogel lens wearers, all three actions (rewetting, cushioning, and lubrication) may be of considerable significance for RGP or PMMA lens wearers. The practitioner should seek to help the wearer find the product best suited for his or her specific comfort needs. Solutions designed for hydrogel lenses generally have lower viscosities, whereas solutions for rigid hard lenses usually have higher viscosities. Although high viscosities can be of distinct benefit in enhancing cushioning action, a solution that is too viscous can cause blurred vision and hinder normal lid movement to an undesirable extent.

Components of Lens Comfort Solutions

Among the polymers used in lens comfort solutions are polyvinyl alcohol, polyvinylpyrrolidone, dextran, and various cellulose derivatives such as hydroxyethyl cellulose, hydroxypropyl cellulose, and hydroxypropyl methylcellulose. Surfactants include certain poloxamer and poloxamine compounds. Other normal components comprise appropriate preservative(s) as well as buffering and tonicity-adjusting agents.

LENS CARE PRODUCTS FOR RIGID GAS-PERMEABLE LENSES

Several types of RGP lenses are marketed (Table 2) and others are under development. Because of their rigid nature, they have certain characteristics in common with conventional hard PMMA lenses. In many cases, care products available for use with the latter have been found to be also suitable for the care of the RGP lenses. Although they may not have optimal characteristics, they are still preferred by many practitioners in comparison to products that were originally designed for use with soft lenses and were subsequently approved by the FDA also for use with RGP materials.

Most categories of products indicated for the care of soft contact lenses are applicable to rigid gas-permeable lenses. These include daily cleaners, wetting and cushioning drops, and weekly enzymatic cleaners. While disinfecting solutions are necessary for RGP lens care, they are often positioned as conditioning solutions. Conditioning is important in providing a hydrophilic lens surface during wear. Because RGP lenses do not withstand heat, saline solutions (both preserved and unpreserved) are not needed for these lenses, except for dissolving enzymatic cleaners for weekly cleaning or rinsing.

Because RGP lenses are not as porous or water absorbing as soft lenses, wearers do not experience the problems that are specific to soft lenses, resulting from preservatives penetrating and concentrating within the lens polymer matrix, which often cause toxic and hypersensitivity-type reactions. However, certain preservatives bind with RGP surfaces and can create clinical problems. Binding may involve ionic and/or hydrophobic interactions.

In addition to accumulation of proteinaceous deposits, such as those occurring on soft hydrophilic lenses, the molecular make-up of many RGP lenses also tends to attract lipid deposits, such as cholesterol esters, wax esters, triglycerides, etc. This is especially true of the more hydrophobic materials such as silicone acrylates with high Dk (oxygen permeability) values. Accordingly, more recent developments in material science related to contact lenses have resulted in materials such as fluorosilicone acrylates and fluorocarbons with purportedly less propensity for deposits.

Wearing rigid lenses is much less comfortable than wearing soft contact lenses. In fact, this is generally perceived to be the major factor limiting the growth of the RGP lens market segment. Consequently, the need for superior wetting, cushioning, and lubricating products is clearly recognized. Superior combination products are also

required for RGP lenses, which provide convenience and enhance product performance.

MULTIPURPOSE SOLUTIONS

Multipurpose solutions are designed to increase wearer compliance and the convenience of product use. Such solutions are not commonly used for the conventional PMMA hard lenses and rigid gas-permeable lenses. They combine two or more basic functions of lens care, including cleaning, disinfection, soaking, wetting, and lubricating. Combination of these functions in a single product may compromise certain aspects of product efficacy. For instance, a solution designed to clean and disinfect may not clean as well the cleaner would alone. However, a combination cleaning and disinfection solution provides the convenience of a single step and would be particularly useful for wearers whose lenses do not attract deposits as readily because of their tear chemistry.

Multipurpose solutions for soft lenses are primarily limited to cleaning and disinfecting. Wetting and lubricating combinations are not a major need because of the inherent hydrophilic nature of soft lenses that makes them comfortable to wear. The technology advances made in identifying preservatives with broader spectrum and capacity along with the ability of chemicals to clean while disinfecting has further simplified care of lenses. Recently, a new product has been developed in a multipurpose solution format that has allowed removal of the rubbing step.

PACKAGING OF CONTACT LENS PRODUCTS

All lens care products are packaged in plastic containers or pressurized metal containers with the exception of enzymatic or disinfecting tablets. The tablets are generally effervescent and packaged in laminated foil or blister packs to ensure adequate shelf life. The packaging materials normally used by the pharmaceutical industry for effervescent tablets are adequate for this purpose. The plastic containers are usually fabricated from low-density polyethylene, high-density polyethylene, or polypropylene materials. Many of the containers are opaque for protection against light. Several types of colorant mixtures, which usually contain titanium, are used in squeeze bottles, and the composition and thickness of the container wall should be designed to allow easy delivery. Another important

consideration is the orifice at the tip, which allows the desired product to flow. For instance, a disinfecting or saline solution needs to be delivered in a large volume of 3 to 5 ml to fill the lens case. A steady stream is desirable and acceptable here, but not for products like wetting, lubricating, and cushioning drops, which are directly instilled in the eye. For these products, the tip has to be designed to allow drop-by-drop instillation. Formulation characteristics such as viscosity and surface tension determine the tip design. The tip must be smooth and rounded as it can come into contact with the eye. The caps for the bottle are normally constructed of polystyrene or polypropylene material.

Because all lens care products, with the exception of the tablet dosage form, have to be sterile, the containers must be sterilized prior to filling unless the process involves form, fill, and seal technology. Containers are usually sterilized by ethylene oxide or gamma irradiation. The latter method is preferred because of stringent government regulations and requirements regarding ethylene oxide residues and its degradation products. Recent years have also seen strict controls regarding the exposure of workers to ethylene oxide and its by-products. Terminal sterilization of the final product is normally not done for lens care products, with the exception of nonpreserved saline solutions in aerosol containers, which are sterilized by gamma irradiation.

ACCESSORY CONTACT LENS PRODUCTS

Accessory contact lens products include cases and devices for cleaning contact lenses and facilitating insertion.

Lens Cases

Lens cases are utilized for disinfection and storage while the lenses are not being worn. Lens cases may have a single compartment with a barrel shape, generally holding 7 to 10 ml of solution, or they may have two compartments in a flat case design, each compartment holding 3 to 5 ml of solution. Lens cases are also used by lens manufacturers as mailers to ship RGP and PMMA lenses in the dry state. Recently, shipping the lenses in conditioning solution has been approved. On the other hand, hydrophilic soft contact lenses are generally shipped in sealed sterile glass vials containing buffered isotonic saline solution. Plastic lens cases are fabricated from polymeric materials such as polyethylene, polypropylene, polysulfone, or polycarbonate.

Devices Facilitating Cleaning

Cleaning devices are useful for lens wearers who lack the manual dexterity to clean lenses with their fingers. They are also used for cleaning lenses that could be scratched easily by fingertips. The consumer versions provide mechanical action by manual swirling or by agitation with the help of an electrical motor or sonication. The professional versions are usually ultrasonic-type devices. None of these devices are capable of removing tenaciously bound protein. The reservoir of the cleaning device is filled with special cleaning fluid or a saline with a few drops of a surfactant-type daily lens cleaner. The device should allow easy lens placement and retrieval and minimize the potential of damage. Lens baskets that allow for rinsing after the cleaning regimen without additional handling are a desirable feature.

Devices Facilitating Lens Insertion

These devices are generally helpful to elderly patients, especially those wearing aphakic lenses. They consist usually of a rubber bulb with a suction cup. They can cause severe corneal damage if used improperly as well as ocular infection if they are not properly cleaned and disinfected.

Future Directions in Lens Care Products

Of the persons fitted with contact lenses (both soft and hard), 40% discontinue wearing them within the first three years. One of the reasons cited is the time and effort required in taking care of them. Therefore, lens care systems will be developed that are simple and more convenient to use, requiring fewer products, and less time. The new products will minimize patient problems through safer preservatives, which are nontoxic even on misuse and do not produce hypersensitization. More effective cleaners as well as products which minimize protein and microbial attachment to lens surfaces will also be forthcoming as well as cleaners that can be instilled in the eye during lens wear to retard deposit formation on extended-wear lenses or to clean lenses while they are being worn. Other future product types may include special artificial tears and comfort drops for older patients who are prone to dry eye. There is also a need for diagnostic products that can detect potential problems before they are manifested clinically. Universal products that could be used with all contact lenses (i.e., hard PMMA, RGP, and soft lenses) may be desirable; however, it is unlikely that such products will be available as different contact lenses vary significantly in their chemical and surface characteristics. The main

emphasis in the future will be on the development of convenient, easy-to-use products that can increase patient compliance and reduce the dropout rate, while ensuring desirable efficacy without compromising product safety. Products specifically designed for the care of disposable and frequent replacement lenses will also be forthcoming.

COMPONENTS OF LENS CARE PRODUCTS

Active Components

Active components play a primary role in the intended use of a product. The active components in lens care products are usually limited to either one or two chemical entities. However, a product may contain several active components if it is designed for multiple functions or indications.

Chemicals with disinfecting capability

Active chemical entities must have bactericidal and fungistatic properties. However, cidal properties for fungal organisms is preferable. The product performance criteria encompassing the types of organisms to be tested, levels of inoculum, and method of testing are defined by guidelines developed by the FDA. Current chemical systems have disinfection times of 4–6 h. This fits with most wearing schedules, because more than 90% of patients remove their lenses overnight between wear periods. Overnight removal seems to help the eye recover from the stress of lens wear. Recently, some efforts to move to shorter disinfection time are under way to increase convenience. The products will require dramatically enhanced disinfection efficacy than currently available or strict compliance to a regimen to achieve the required level of disinfection.

Surface-active and other agents with cleaning capability

Surfactants of various types have been traditionally used for cleaning conventional PMMA hard lenses. They are considered effective in removing surface deposits on these lenses, such as cosmetics, hair spray, mascara, etc. However, they are not effective in removing tenaciously bound deposits (e.g., proteins, lipids, lipoproteins, mucoproteins) that are commonly encountered with soft hydrophilic contact lenses and rigid gas-permeable lenses. Such deposits are more effectively removed by products containing enzymes, strong oxidizing agents, or suspended abrasive (deposit-shearing) particles. The types of surfactants used and representative products on the market are discussed later under Products for

Cleaning Soft Contact Lenses. A few other agents such as citrate and some phosphates have been used as cleaning agents.

Components with wetting, lubricating, and cushioning capabilities

Polymers and surfactants are the two main classes of compounds used as wetting, lubricating, and cushioning agents. Contingent on the nature of the specified polymers, they are used in various combinations to achieve desired product characteristics.

Both synthetic and natural polymers are commonly used in lens care products. These agents can provide a cushioning effect as a result of increased viscosity. The need for products with such action is greater for the wearers of conventional hard PMMA lenses and rigid gas-permeable lenses, for these are inherently not as comfortable as soft contact lenses because of the lens design and the physiochemical nature of the polymers. Viscosity-building agents provide the necessary initial coatings on the lens surface before it is coated by natural tear components. Besides contributing to viscosity, the ability of polymers to adsorb on lens surfaces and to elicit surface-active (wetting) properties are important considerations.

Surface-active agents are adsorbed on the lens surface and allow ready spreading of tears when the lenses are inserted, thus making them more comfortable to wear. The use of surface-active agents to impart wettability to the lens surface is of lesser value for products used for hydrophilic soft contact lenses, which have built-in wetting characteristics because of their water content. Addition of surfactants may be of value, however, in retarding deposit formation or for cleaning while the lenses are worn. The methodology for measuring both advancing and receding contact angles, as an indication of wetting efficacy, has been standardized for contact lenses. Various polymers have different degrees of wettability as measured by contact angle using a goniometer. However, the *in vitro* contact-angle measurement of contact lenses made from various polymers is of little clinical value. No discernible differences in *in vivo* contact angle can be detected on insertion of a contact lens in the eye following a few blinks that result in coating the lens surface with tear components. Surfactants are usually combined with polymers to impart substantivity and cushioning characteristics. The types of polymers and surfactants used in representative products in the market are discussed later under Products for Enhancing Soft Contact Lens Wear Comfort. Again, the need for surface-active agents which can facilitate wetting of lenses and spreading of tears is greater for

PMMA and rigid gas-permeable lenses because of their hydrophobic surface characteristics.

Ancillary Components

Preservatives

Preservatives are used in almost all multidose contact lens products. Because the potential for misuse of products by lens wearers is significant, preservatives prevent the potential proliferation of microorganisms. A contaminated product could ultimately lead to an ocular infection and possible loss of eyesight. Preservatives are considered active components when incorporated in products for the purpose of disinfecting contact lenses. The preservative must possess the antimicrobial activity described in the FDA guidelines for contact lens care.

The FDA has issued guidelines for preservative efficacy, which include an additional safety factor to compensate for potential misuse of products. These requirements are more stringent than the requirements of the *United States Pharmacopeia* (USP) for preservative efficacy. The FDA requires rechallenging the preserved products on day 14 with a defined inoculum of microorganisms; this is not required by the USP. The preservatives generally used are mainly the same as those used for thermal or chemical disinfection of contact lenses. The concentrations could be different than in the chemical disinfection of contact lenses. The concentration is generally higher in cleaners and comfort-enhancing solutions because of possible binding with polymer and surfactant components, which result in a decrease in preservative efficacy.

Different countries have different standards for preserving contact lens solutions; the requirements of the *British Pharmacopoeia* are the most stringent. Many marketed products do not meet these requirements. The three major preservative efficacy tests, which must be considered in developing products, are delineated in the United States Pharmacopoeia (modified test to meet FDA guidelines), the *British Pharmacopoeia* and the *German Pharmacopoeia* (DAB). In terms of difficulty to comply, the *British Pharmacopoeia* test is the most stringent and the modified USP test the least stringent. The main differences among the test requirements are the exposure times and use of *Escherichia coli* as a challenge organism. The *British Pharmacopoeia* utilizes a 6-h criterion for antimicrobial activity, whereas the USP uses a 14-day criterion. Recently, an International Standard has been approved which is comparable to the US FDA procedure. The types of preservatives used are

described in the tables related to various product categories.

Buffers for adjusting pH

The use of buffers and pH adjustment is an important consideration in lens care products. It is a general practice that all products which are likely to come in direct contact with ocular tissues should be buffered for ocular comfort around physiologic pH and preferably in the range 6–8.0. The most commonly used buffers in contact lens care products are phosphates and borates. Buffers used occasionally are acetate, citrate, and others. Besides buffers, sodium hydroxide and hydrochloric acid are generally used to achieve a desirable pH in the final product. They are also used to adjust the final pH in products, which do not have any buffering system. The selection of an appropriate buffering system should consider the pH necessary for optimal performance of the product, as well as products stability and potential incompatibility with other components of the product.

Although it is desirable to have a product as close to physiologic pH as possible, it is often essential to formulate a product outside the physiologic pH range in order to achieve the desired stability of the product, optimal efficacy, or appropriate solubility of active and ancillary components. Products formulated outside the physiologic pH range should have low buffer capacity to allow quick equilibration to tear pH by the bicarbonate buffer system present in the tears. The maintenance of pH close to physiologic pH is essential for products intended for soaking and disinfection of hydrophilic soft contact lenses in order to maintain the parameters of some lenses, especially those belonging to FDA Group 4. Such changes in parameters can cause not only discomfort but can also produce blurred vision.

Tonicity-adjusting agents

Contact lens products should be formulated as closely as possible to the tonicity of tears. This is important for optimal comfort. Prolonged exposure to hypotonic solutions can induce edema in corneal epithelial cells, which can cause blurred vision and discomfort, whereas prolonged exposure to hypertonic solutions can cause corneal epithelial cells to shrivel and cause discomfort by exposing nerve endings. None of the currently available contact lens solutions have been responsible for such symptoms as most of them are formulated close to isotonicity and many contact lens products have minimal contact with the cornea. Nevertheless, maintaining the tonicity of products close to the isotonic value of 280 (± 50) mOsm/kg is important for optimal comfort as well as for maintaining the integrity of certain hydrophilic soft

contact lenses (especially those belonging to FDA Group 4). The type of compounds commonly used for imparting isotonicity include buffering agents, sodium chloride, potassium chloride, propylene glycol, mannitol, dextrose, etc.

Viscosity-building agents

Viscosity-building agents such as synthetic and natural polymers are used as active ingredients in solutions providing comfort and rewetting products. However, they are also used as ancillary agents in contact lens cleaning products. These agents allow better cleaning of contact lenses by enhancing the contact of the cleansing agent with the soiled lens and by facilitating the process of rubbing the lens between fingers or between the palm of the hand and an index finger. Highly viscous or gel-type cleaners are also available. However, they are not very popular as they are difficult to rinse and may cause ocular irritation. The types of polymers used as ancillary agents are the same as those used for solutions providing comfort or rewetting solutions.

PHARMACEUTICAL TECHNOLOGY CONSIDERATIONS IN PRODUCT DESIGN

With few exceptions, contact lens products are sterile solutions. The sterility requirements are important because of the potential of sight-threatening ocular infections. The sterility test procedures and pass–fail criteria as described in the *United States Pharmacopeia* must be met for FDA approval of contact lens products. The technology practiced in the development of pharmaceutical products, such as injectable and large volume intravenous fluids, is generally acceptable, with somewhat less stringent requirements for contact lens care products because most of these products do not come into direct contact with the eye (i.e., its interior cells and fluids). Products that are packaged in unit dose containers or multidose pressurized aerosol containers do not have to be preserved. However, multidose products other than aerosol containers should be preserved and should pass the FDA preservative efficacy test. Manufacturers intending to develop lens care products should consult with the FDA for the latest guidelines.

Apart from solutions, there are other pharmaceutical dosage forms for contact lens products that are less commonly used. They include gel- and suspension-type cleaners, powders, and tablet dosage forms for enzymatic cleaners or disinfectants. All of these products are formulated as sterile products with the exception of powders and tablets. These, however, must comply with

USP requirements for bioburden with added specifications for absence of colony-forming units of *Staphylococcus aureus* and *Pseudomonas aeruginosa* among other organisms. The choice of components in formulating these products is much more restrictive in comparison to pharmaceutical products intended for systemic or topical use because of the potential of causing irritation to the sensitive ocular tissues.

Chemical components must be nonirritating and compatible with ocular tissue as well as with lenses. The choice of components for tablets, such as binding and lubricating agents, is much more restrictive, as these ingredients must be soluble and form a clear solution when dissolved in saline solutions. Formulation components generally used and acceptable for ophthalmic products may be unacceptable for contact lens products, as many contact lens materials can concentrate components used in contact lens products as much as several hundredfold. On insertion of the lenses, these ingredients are released in toxic levels to the cornea, causing minor to severe ocular reactions. The binding and release of ingredients can be further complicated by the condition of the lens. For instance, thimerosal and chlorhexidine, commonly used ingredients in contact lens products, concentrate differently in new, deposit-free lenses as compared to used lenses with protein deposits on the surfaces. Appropriate studies must be designed to address these issues to minimize the potential of ocular irritation. Certain ingredients such as thimerosal, when used initially are well tolerated. However, on prolonged exposure, some lens wearers develop hypersensitivity, resulting in intolerance of thimerosal products. Such intolerance is difficult to predict and currently no satisfactory method is available to predict delayed hypersensitivity-type reactions, which are modulated immunologically. The commonly used guinea pig maximization test is not predictive of delayed hypersensitivity reactions.

As noted previously, formulating products close to physiological pH is desirable. However, for optimal product performance or meeting regulatory requirements, it is sometimes necessary to formulate products outside the physiologic pH range. Sorbic acid, a commonly used preservative for lens care products, is a marginally effective antimicrobial agent with a pKa value of 4.8. A product fails the FDA preservative efficacy test if it is formulated around a physiologic pH of 7–7.4 at a concentration of 0.1 sorbic acid normally used in marketed products. To maximize its antimicrobial activity without compromising ocular comfort to a significant extent, it is necessary to formulate such products around pH 6.5–6.8. Thus, a consideration of the dissociation constants of preservatives is essential as the antimicrobial activity of

many preservatives depends on the undissociated species, which should be present in an adequate amount at physiological pH without causing ocular irritation.

The product design should also consider the nature of the lens polymer and its surface charges. For example, FDA Group-4 lenses, which carry negative surface charges, can react with positively charged product components, resulting in severe ocular toxic reactions. Such toxic reactions can be prevented by incorporating nonionic surfactants to form micelles with the cationic components, thus minimizing surface interactions and toxicity. If a cationic agent in the product is a primary disinfecting agent, efforts to minimize toxicity or surface interactions often result in reduced antimicrobial performance. It is, therefore, essential to minimize surface interactions and yet have a product, which meets the requirements for disinfection or preservation.

The hydrophilic–lipophilic balance (HLB) and molecular dimensions of a preservative should also be considered in the design of contact lens products. For example, chlorobutanol (a nonionic preservative used in ophthalmic products) penetrates into the matrix of rigid gas-permeable (RGP) lens materials because of the molecule's substantial lipophilic characteristics. The preservative present in the lens matrix may change the parameters or may be gradually released during wear, causing irritation and toxicity to the corneal cells. On the other hand, the molecular dimensions of a preservative are very important in designing a product for hydrophilic, soft contact lenses. Generally, preservatives with a high molecular weight and appropriate molecular configuration are less likely to penetrate the porous matrix of hydrogel lenses. Products containing preservatives like Dymed and Polyquad, with molecular weights above 1000, are currently available.

LIPID EXCIPIENTS IN PHARMACEUTICAL DOSAGE FORMS

Alan L. Weiner

Alcon Research, Ltd., Fort Worth, Texas, U.S.A.

THE ROLE OF LIPIDS

Biologically, lipids function as structural elements in plants and animals, transport vehicles, mediators of chemical reactions, energy sources, and as messenger molecules. It is from an understanding of these functions that lipids have been applied to pharmaceutical applications. Lipids can be appropriately manipulated to conform to various physical states such as solutions, suspensions, emulsions, creams, gels, or solids. Because a combined lipid-drug formulation will present a very different conformation and/or molecular size than the drug alone when introduced into a biological environment, changes in both the distribution and the recognition of the drug by the host defense system will occur. These changes may be either intended or undesired.

Overall, the uses of lipids in pharmaceutical dosage forms can be grouped into four categories: 1) improvement in the processing or stability of the formulation in the preferred physical state; 2) enhancement or reduction in cellular or systemic absorption of the drug from the formulation; 3) more effective drug targeting; and 4) sustained or more controlled delivery of the drug. In this article, the problems and opportunities in utilizing lipids for these applications will be explored from various aspects of pharmaceutical formulation, analysis methods, and other commercial issues.

CATEGORIES OF LIPIDS IN PHARMACEUTICAL PREPARATIONS

The principal material categories discussed in this article are illustrated in Fig. 1. Categories shown are: fatty chain acids, salts, alcohols or amines, oils and waxes, phospholipids, glycolipids, neutral lipids, and nonlinear chain compounds, such as sterols.

Fatty Acids and Derivatives

Fatty acids, salts, alcohols, and amines have been utilized in pharmaceutical formulations. Fatty acids are present in cosmetics, ointments, and suppositories and are used in

tablet coating applications and as carriers in inhalant products. Fully saturated fatty acids are solid materials at chain lengths above eight, whereas longer chain polyunsaturated forms may exist as liquids, unless the double bonds are conjugated. Fatty acid salts are used widely in tableting applications and often include magnesium, calcium, and aluminum stearates. The handling properties and physical interaction with other solids make them ideal as conditioning agents to effect even distribution of particles, improve compressibility, and control the eventual release of active agent. The fatty alcohols, including cetyl and palmityl alcohol, are well known and are used extensively in ointments or creams as an emollient or emulsion modifier. Fatty amines are generally utilized as precursor compounds in coupling reactions to produce lipophilic drug derivatives. Fatty amines, like the acids, are solid at higher chain lengths and insoluble in aqueous solution. Finally, aldehydes of fatty chain compounds have application in fragrances and flavorings. The unsaturated liquid forms of fatty aldehydes are most often employed.

Oils, Waxes, and Neutral Lipids

Fatty acids, when esterified to glycerol, form mono-di- and triglycerides. Depending on the number of substituted fatty acids, the carbon chain lengths and the unsaturation level, the resultant product may exist in either liquid state (oil) or solid state (wax). Products in this category may either be naturally derived or synthetically produced and, thus, a wide diversity of products is commercially available. Oils have drug-carrying and solubilization functions in oral, topical, or injectable products. Waxes are presently used in topical and oral preparations to improve desired physical properties and control dissolution of the final product. Common materials in this group that are present in commercialized pharmaceutical preparations include castor oil, hydrogenated vegetable oil wax, paraffin, carnauba wax, white wax, olive oil and olive oil ethyl ester, mineral oil, petrolatum, cetyl ester wax, and beeswax. Neutral lipids, such as steroids, are also of value in pharmaceutical practices. For example, cholesterol and cholesterol esters can be exploited to broaden liposome phase transitions and to allow easier manipulation and or emulsification.

Fig. 1 Lipid structures.

Phospholipid Compounds

The complexity of glycerides advances by modification of the terminal hydroxyl with phosphate linked head groups to form phospholipids. Common phospholipid head groups include choline, ethanolamine, serine, inositol and inositol phosphates, glycerol, and glycerol esters. As with the triglycerides, numerous species are possible by various

combinations of different headgroups and fatty acyl substitution at the 1st and 2nd positions of the glycerol backbone. Fluidity differences are evident as a function of the gel to liquid crystalline transition temperatures (Table 1). Solubility of phospholipids is intimately linked to the conformation of the aggregate material rather than strictly a chemical function of the molecule. Monoacyl phospholipids, which tend to form micelles, are usually more readily

Table 1 Transition temperatures of common phospholipids

Head group	Fatty acid component	Transition temperature (°C)
Hydrogen (phosphatidic acid)	Dimyristoyl	51
	Dipalmitoyl	67
Choline	Dioleoyl	−22
	Natural (mixed unsaturated)	−15
	Dilauryloyl	−1.8
	Dimyristoyl	23
	Dipalmitoyl	41
Ethanolamine	Distearoyl	55
	Dimyristoyl	50
	Dipalmitoyl	66
Glycerol	Dioleoyl	−18
	Dilauryloyl	4
	Dimyristoyl	23
	Dipalmitoyl	41
	Distearoyl	55
Serine	Natural (mixed unsaturated)	7
	Dimyristoyl	38
	Dipalmitoyl	51
Sphingomyelin	Natural	32
	Dipalmitoyl	41
	Distearoyl	57

soluble in aqueous solution. Diacyl phospholipids generally form liquid crystalline suspensions as long as the temperature is held at or above the phase transition. Overall, because phospholipids are amphipathic, they function well as emulsifying or dispersing agents. Although most often found in topical products, phospholipids have been employed in oral capsule formulations as well as in liposomal parenteral formulations.

Glycolipid Compounds

Glycolipids include compounds formed by the linkage of a sugar moiety to a glyceride backbone. Classical glycolipids such as glycosyl glycerides or ceramides are not common in pharmaceutical preparations primarily due to low abundance and high cost; however, glycosyl modifications can be used to impart targeting mechanisms to aggregate lipid formulations.

LIPID CONFORMATION

The colligative and solubilizing properties of lipids have been known since the early part of the 20th century. What had been perceived as clusters of amphipathic

molecules (soaps) in aqueous solution are now better understood as micelles (1–3). Micellar solubilization of pharmaceuticals is now a familiar classical technique, which has been reviewed in detail (4, 5). Additional understanding of drug dissolution and impact of lipid conformations can be gained from studies that utilized macro and microemulsions to solubilize drugs (5–9).

Beyond the concept of micelles and emulsions, the combination of lipid and aqueous components can result in formulations that exhibit a variety of physical states. These result from lipid orientations, which may be either random, in thermotropic crystalline lattices, or in aggregate structures with long-range order (lyotropic liquid crystals) (10). Figure 2 illustrates possible lipid conformations with micellar and emulsion/surface monolayer orientations being the earliest of recognized microstructures. Lipid molecules are also capable of packing tightly together to give more ordered states, such as a bilayer. In fact, depending on the components in the formulation, lipids may contribute to distinct phase diagrams containing up to at least six different regions (11). The “neat” or lamellar (liposomal) phase (12) physically can appear as a suspension to a highly viscous cream (13), depending on the final volume. Lamellar organizations further include liquid crystalline,

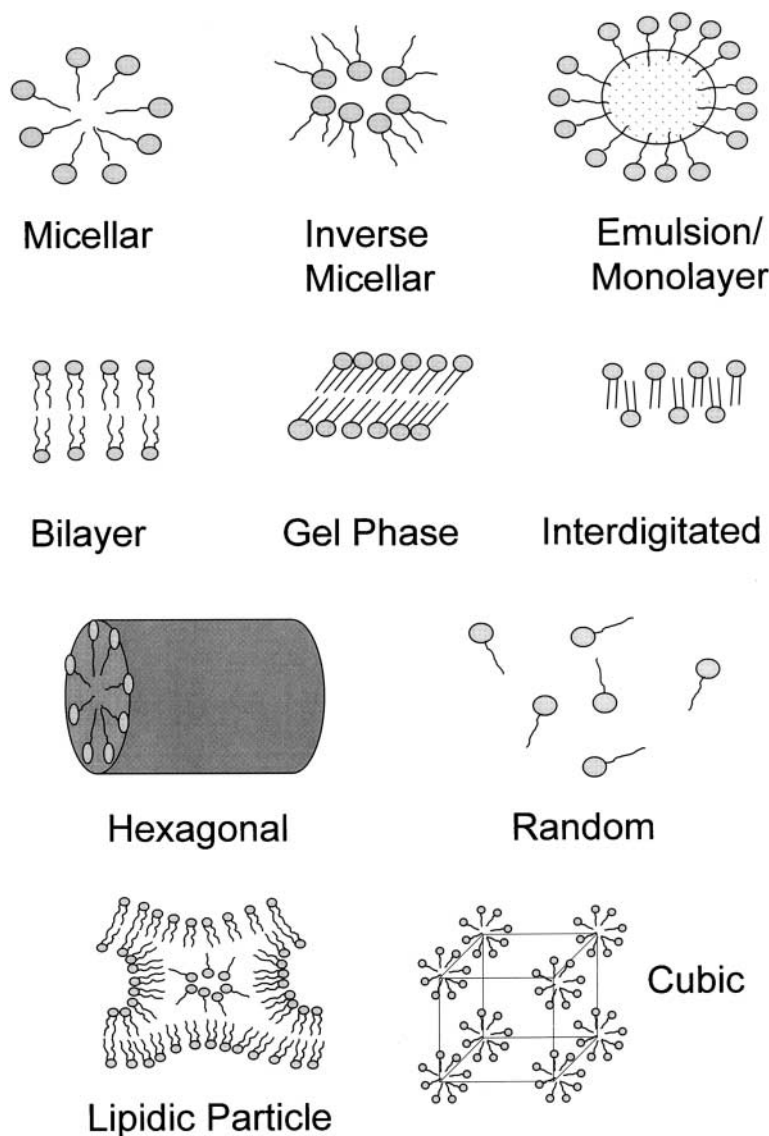

Fig. 2 Conformational states and spatial organizations of lipids. Small circles indicate the polar head group region of the molecules, whereas hydrophobic chains are represented as single lines.

gel state, and interdigitated phases. The middle phase (hexagonal) is a cylindrical arrangement with a hydrocarbon core, surrounded by an interfacial layer of hydrated polar groups. This orientation can be reversed to yield the hexagonal II structure, which appears stiff, and suspends as hard particles in water and will not dilute in additional aqueous solution. Lipids can also organize into cubic structures that appear clear, brittle, and viscous in character (14). Mixed conformations of lipids have also been observed, as is the case for lipidic particles, with inverse micelles distributed between a lamellar matrix.

These different aggregated states are sometimes reached by transitions through other phases simply by changes in temperature or by nature of the external environment (such as solvent concentration). Phase transitions of lipids can be regulated by changes in pH, temperature, cation concentrations, and presence of amphipathic additives. A comprehensive database on lipid phase transitions has been recently compiled by Caffrey (15). Polymorphic transitions are common in the preparation of lipid-containing formulations and can account for the differences in physical handling properties of the material during manufacture in which varying

amounts of solvents, or energy input, are encountered at the different process steps. Geometric preferences of lipids can be better understood by considering the relative volume occupied by each portion of the molecule. Cullis et al. (16) and Gruner et al. (17) have described such molecular shape analysis of lipids in detail (Fig. 3).

The various macromolecular aggregates of lipids also make it possible to associate with drugs through physical entrapment. In these cases, the concentration of lipid associated drug is dictated by the size or conformation of the drug and the spaces created in the lipid aggregate. Entrapment levels of drug can vary from less than 1% to as high as complete encapsulation. Excluding chemical interactions or solubilization phenomena, drug encapsulation efficiency is linked to both the lipid conformation and the manufacturing method, which juxtaposes the two components. This is particularly true of liposome formulations in which factors of temperature, pressure, solute concentration, solvent volumes, or energy application all contribute to the final amount of drug incorporated within the lipid matrix (18).

MANUFACTURING OF LIPID-CONTAINING PRODUCTS

Manufacturing issues should be evaluated as part of overall lipid formulation development. Although lipid addition may be desirable for pharmacological purposes there are often commercial issues which present hurdles to eventual marketing. Among those factors are the availability and cost of raw materials, handling of intermediate mixed-phase systems, particulate control, stability of the lipid ingredients, sterilization, packaging interactions, qualification of noncompedial ingredients, and development of validated methods for analysis of either raw material or product.

Availability and Cost of Lipid Raw Materials

For commercial formulations, raw material sources should be of high purity and quality consistently meeting defined specifications, preferably compendial when available. Fortunately, high-purity lipids have

Fig. 3 Geometric models representing packing behavior of micelles, inverse micelles, and lamellar structures. Lipid molecules with domains that occupy a large lateral distance compared to adjacent domains of the molecule will conform to corresponding shapes and packing behavior. Micelles and inverse micelles approximate cone shape, whereas lamellar systems resemble cylinders. (Adapted from Refs. 16 and 17.)

become increasingly available in large supply, and in particular, phospholipid supply has advanced in recent years due to the approval and marketing of parenteral liposome formulations.

Large supply of naturally derived lipids can be obtained from plants in which many oils and fatty acids can be readily extracted and purified. Animal sources (e.g., eggs or milkfats) are used to derive complex lipids such as phospholipids and cholesterol. Yield from natural sources is dependent on the weight-percent composition and the efficiency of the extraction procedure. The constitution of fatty acids in vegetable oils varies widely from different sources (19). For example, oleic acid is present at 64.6% by weight in olive oil but is present at only 0.7% in palm kernel oil. Similarly, castor oil triglyceride is comprised of almost entirely ricinoleic chains. There are numerous raw material suppliers of oils and oil fractions worldwide. As such, the relative cost of bulk purified fractions and their derivatives such as salt forms and alcohols is quite low (\approx \$50–150/kg). Costs for high purity synthetic phospholipids ($>97\%$) continue to drop when compared to prices 8 to 10 years earlier (18, 20, 21). This is primarily due to the advent of marketed liposome products. Phospholipids are available worldwide from companies such as Genzyme (U.S./U.K.), Avanti Polar Lipids (U.S.), Matreya Inc. (U.S.), American Lecithin Co. (U.S.), Lipoid GmbH (Germany)/Vernon Walden (U.S.), Lucas Meyer (Germany), Nichiyu Liposome/Nippon Oil and Fat (Japan) and Northern Lipids (Canada). Also now available in larger supply are PEGylated phospholipids, lysopholipids, and various cationic lipids used in gene therapeutic applications.

Compounding of Lipids into Formulations

Lipids may be supplied either as lyophilized or dried powders, as liquids, or dissolved or suspended in an appropriate solvent. Dried powders are typically waxy or sticky in character, making aliquoting of the product troublesome. Lipid lyophilates can also be hygroscopic, thus presenting some difficulty for fluidized bed operations. Fluid bed applications however, may be successful if the concentration of lipid is held fairly low (22).

Handling of lipid products in a liquid state allows for more accurate compounding. Solubilization vehicles may involve dissolution into either polar or nonpolar solvents or surfactant solutions. Aside from safe handling, a primary concern when introducing lipids

from solvent environments is the compatibility of the solvent with processing equipment, in particular the gaskets and seals found in the pumps, transfer lines, mixers, and extractors. Elevated temperatures, which are used to dissolve or maintain the phase transition of the lipid or to initiate solvent evaporation, can further induce problems for gaskets and seals. In systems with nonvolatile solvents and detergents, removal of the dissolution vehicle can be achieved with flow centrifugal separation, chromatography or diafiltration.

Introducing a lipid-containing solvent to an aqueous solution of drug will require some means for energy input to mix the components, whether by simple rotating blade stirring, more vigorous homogenization, or milling, by sonication and filtration, or by high-pressure extrusion (23). Unless cosolvation is achieved a suspension of nonmiscible aqueous and nonpolar phases will offer more resistance to flow and may present problems for extrusion through filters, which tender a surface that is of opposite character to one of the phases. Binding of active agent, such as proteins, must also be considered (24). The conformational state of the lipid and the concentration also will govern the workability of the formulation. Lamellar orientations will flow fairly readily at concentrations below about 400 mg/ml whereas cubic or hexagonal phases will present difficulty even at very low concentrations.

Particulate and Particle Size Control

For lipids dissolved in solution, particulate control may be necessary, depending on administration route. For parenterals the large- or small-volume parenteral particulate tests of the USP are applicable, as would be the Ph. Eur. clarity test and JP foreign matter insoluble test. For suspended or opaque lipid formulations, compendial particle size tests and specifications for suspensions will apply (i.e., light obscuration or microscopy). Size reduction of lipid formulations can be achieved with a variety of processing equipment including paddle stirrers, homogenization and high shear mixers, Microfluidizer, colloid mills, ultrasonic and piezoelectric emulsifiers, and pressurized filtration or membrane extrusion.

Lipid Stability

A characteristic of lipid products, particularly those with unsaturated lipids is peroxide formation with oxidation (25). Free radicals such as ROO^\bullet , RO^\bullet , and OH^\bullet can

damage the drug and induce toxicity. Lipid peroxides may also form due to autoxidation, which increases with unsaturation level. Hydrolysis of the lipid may be accelerated due to the pH of the solution (26) or from processing energy such as ultrasonic radiation (27). Antioxidants (i.e., α -tocopherol, propyl gallate, ascorbate, or BHT) may be required.

Sterilization Methods

Because of possible oxidation, steam or heat sterilization of lipids may not be an attractive option. Validations at nonstandard autoclave cycles or F_0 values may prove valuable. In some instances, as in ophthalmic ointments made with white petrolatum or oleagenous components, the base can be sterilized by dry heat (160–180°C for 1–3 h) and combined aseptically with the sterile drug and additives (28). Ointments with lipids such as lanolin, petrolatum, and mineral oil have been terminally sterilized by cobalt-60 gamma irradiation with success (28–30). In less viscous solutions, end terminal filtration with aseptic fill is often necessary, requiring justification to regulatory authorities for lower sterility assurance levels. High pressures may be required to force lipid through membranes, thus adequate filter integrity checks are critical. High-pressure extrusion through straight channel membranes (polycarbonates/ceramics) may reduce the pressures and improve flow rates (23).

Packaging and Processing Surface Considerations

Lipids will be attracted to hydrophobic surfaces where losses might be expected. Overall binding will be affected if the molecule also contains ionic regions. Generally, lipids are chemically compatible with most plastics or glass used in packaging. Residual solvents that partition into the lipid phase may interact with plastic resins such as polystyrene or polycarbonate or with rubberized seals. Extractables from plastic packaging may be accelerated by the presence of lipid. Extraction of silicone polymer into lipid phases also occurs from silanized surfaces or coated gaskets. Compendial tests and regulations on extractables and impurities will apply here. Presence of metals coming from process or package surfaces are a potential source of catalysis leading to degradation of lipid components. In addition, reducing oxygen headspace should be considered to minimize potential degradation. Inert gas purging can improve lipid stabilities.

ANALYSIS OF LIPID PHARMACEUTICAL PRODUCTS

Because lipids exhibit primary through quaternary conformations, the analysis of lipid-containing pharmaceutical products must therefore involve both chemical and physical determinations to define the product on the molecular level as well as the aggregate state of the product. Stability-indicating assays can be developed from both approaches.

Chemical Determinations

Lipids can be measured by standard analytical methods such as wet chemistry, HPLC, thin-layer chromatography, and gas chromatography (31). Because lipid formulations may have several components and because the formulation may have an overall aggregate structure, it is usually necessary to develop further strategies for isolation and detection of the lipid ingredients (32). Dissociation of the individual components using temperature, solvents, detergents, reducing or oxidizing agents, or mechanical disruption prior to analysis may be necessary. Further separation or extraction of the components before analysis is required if interference is encountered. With lipid solvent extraction, there is a greater likelihood for losses of material. More often than not, a combination of techniques will be required for validation of the product. There are worldwide compendial procedures for analysis of various lipids by wet chemistry procedures to determine concentration, end group analysis, acid value, hydroxyl value, iodine value, and saponification value. A listing of the USP/NF methods for lipids is shown in Table 2.

HPLC Methods

Analysis of nonpolar lipids by HPLC is best carried out using normal phase columns. However, for mixed phases with polar drug or drug within an aqueous phase some compromise may be necessary. Good separation of polar and neutral lipids with a C8 column and a four-solvent mobile phase has been reported (33). Elution of neutral lipids like triglycerides from C18 columns is slow, however, good resolution can be achieved. Mobile-phase development is usually necessary to effect a high degree of separation and resolution of similarly eluting components (34). Heated columns are beneficial for increasing temperature above the phase-transition temperature of the lipid and thus minimize clogging. Lipids with predominantly saturated chain lengths will

Table 2 USP 24/NF 19 methods for lipids

Lipid category	Method
Steroids and steroid esters	Cholesterol, betamethasone, calcifediol, cholcalciferol, clocortolone pivate, cortisone acetate, dehydrocholic acid, desoximetasone, desoxycortisone (acetate and pivalate), dexamethasone, difluorosone diacetate, dihydrotachysterol, dydrogesterone, ergocalciferol, estradiol, estriol, conjugated estrogens, estrone, estropipate, ethynodiol diacetate, fludrocortisone acetate, flumethasone pivalate, flunisolide, fluocinolone acetate, fluocinonide, fluoromethalone, fluoxymesterone, flurandrenolide, halcinonide, hydrocortisone, levonorgestrel, medroxyprogesterone, meprednisone, mestranol, methylprednisone, methyltestosterone, mibolerone, mometasone furoate, nandrolone (decanoate and phenpropionate), norethynodrel, norgestrel, oxymethalone, prednisone, progesterone, rimexolone, spironolactone, stanozolol, testolactone, testosterone, trenbolone acetate, and triamcinolone
Fatty-acids, salts and esters	Aluminum monostearate, calcium stearate, ethyl oleate, isopropyl myristate, isopropyl palmitate, magnesium stearate, oleic acid, polyoxyl 40 stearate, propionic acid, sodium stearate, stearic acid, purified stearic acid, and zinc stearate
Fatty alcohols	Benzyl alcohol, butyl alcohol, cetostearyl alcohol, cetyl alcohol, cetyl esters wax, lanolin alcohols, octyldodecanol, oleyl alcohol, and stearyl alcohol
Oils and oil esters	Almond oil, castor oil, cod liver oil, corn oil, cottonseed oil, diacetylated monoglycerides, ethiodized oil injection, glyceryl behenate, glyceryl monostearate, hydrogenated castor oil, hydrogenated vegetable oil, light mineral oil, mineral oil, mono- and diglycerides, mono- and diacetylated monoglycerides, oil-soluble vitamins, olive oil, orange flower oil, peanut oil, peppermint oil, perflubron, persic oil, polyoxyl 35 castor oil, polyoxyl 40 hydrogenated castor oil, rose oil, safflower oil, sesame oil, soybean oil, squalane, tocopherols excipient, vitamin E, and vitamin E PEG succinate
Phospholipids	Lecithin
Waxes	Caranuba wax, emulsifying wax, hard fat, hydrophilic ointment, hydrophilic petrolatum, microcrystalline wax, paraffin, petrolatum, rose water ointment, synthetic paraffin, white wax, yellow ointment, and yellow wax

have poor ultraviolet (UV) absorption even at the lower wavelengths (190 nm). Alternative detectors should then be considered.

Thin Layer Chromatography

One- and two-dimensional thin-layer silica gel chromatography remains a cornerstone of lipid analysis (31, 35). Sensitivity by this method is typically as low as 2 µg/spot. Lipid visualization can be achieved by many methods, including iodine vapor or charring of plates following exposure to sulfur-dichromic acid, cupric reagents, Phospray, or α-naphthol. Other useful reagents include stains and dyes such as fluorescamine, rhodamine 6G, bromothymol blue, molybdenum blue, phosphomolybdic acid, and silver nitrate, which may be impregnated into the silica. Validation of lipid

purity and quantitation is performed using gel or plate scanners.

Gas Chromatography (GC)

Capillary and packed (GC) columns are of value in the analysis of complex mixtures of lipids. The best capillary column length will depend on the complexity of the material injected, however, 30-m columns are often employed. In packed columns, many types of stationary phases are available for lipid separation, and these include silicone and alkylated or cyanogenated derivatives, polyesters, polyglycol, and carboranes. It is also common to derivatize the fatty-acid side chains to the corresponding methyl esters by reaction in BF₃/methanol prior to chromatographic analysis to achieve more distinct and uniform separations.

Physical Determinations

The aggregate states of lipids are discernable from measurements provided by a host of analytical devices, which yield information on physical properties. These techniques may also be used to give clues as to the interaction of the lipid carrier and the drug.

Particle sizing

Lipid particulate analysis can be achieved with most commercial laser particle counters. Compendial requirements for suspensions also allow for sizing via electron microscopy determinations, which can provide for qualitative assessments in addition to quantitation. Lipid suspension particles can be detected by negative-stain, freeze-fracture, critical-point drying and scanning techniques.

Nuclear magnetic resonance (NMR)

NMR is a valuable technique in the analysis of lipid phases (36). More specifically, proton, deuterium, carbon-13, fluorine-19, and phosphorus-31 NMR have been utilized for analysis of the dynamic and motional properties of lipids, lipid diffusion, ordering properties, head-group hydration, lipid asymmetry, quantitation of lipid composition, and head-group conformation and dynamics. Cullis et al. (16) and Gruner et al. (17) have shown the importance of P-31 NMR as a tool in the determination of phase properties and lipid asymmetry and the identification of bilayer, hexagonal, and isotropic phases.

Electron spin resonance (ESR)

ESR is used to give information on the local environment of a lipid molecule (37). In normal state these molecules inherently do not exhibit ESR spectrums. However the necessary signal can be generated from reporter labels such as nitroxide or doxyl probes, which can either be linked directly to the lipid molecule or prelinked to a lipid chain and then partitioned into the lipid aggregate formulation. Data from ESR spectrums are valuable for determining molecular properties of the formulation, such as phase transitions and separations, order parameters (anisotropy), polarity, lateral diffusion, segregation and clustering, surface and transbilayer potentials, permeability and internal volumes, surface determinants (antigens), pH gradients, lipid asymmetry, flip flopping, and fusion.

Differential scanning calorimetry

Differential scanning calorimetry is a well known technique in the study of the thermal behavior of lipids

and can be used to assess purity and stability of lipids, perturbation of aggregate structures, phase transition temperatures, lipid mixing behavior, and influence of other molecules and ions on structure (38).

X-ray and neutron diffraction

Diffraction patterns of lipid solutions can yield strong evidence for the presence of specific repeating conformational structures as well as the spacing between lipid molecules in organized films or layers (12, 39–41).

Spectroscopic analysis

Appraisals of the optical properties of lipid solutions and dispersions will provide information on concentrations, aggregation and stability, phase transitions, densities, and repeating structures (42–44). Measurements of refractive index, scattered light intensity (polarized and depolarized), and birefringence are relatively easy laboratory methods on which certain product specifications may be based. Also, fluorescent techniques can readily provide information on lipid movements and transfer of lipid between particles (45, 46).

COMMERCIAL AND EXPERIMENTAL LIPID DOSAGE FORMS

The key purposes of lipid materials in dose forms include: 1) improving the solubility or physical workability of the drug for ease of administration or to enhance stability; 2) augmentation or reduction in absorption of the drug from the formulation; 3) specific drug targeting to maximize response and minimize side effects; and 4) controlled or slow delivery of the drug from the formulation. Currently, the largest use of lipids in pharmaceuticals is in products for oral or topical dosage administration, although there is growing use in parenteral, pulmonary and nasal products.

The mechanics of drug delivery from lipid systems is governed by five structural features: primary structure, that is, chemical or molecular interactions, secondary organization into aggregate structures such as inverse micelles, tertiary organization of the aggregate projected into three dimensions such as three dimensional inverse micelles or hexagonal phase tubules; quaternary associations, agglomeration or interaction of the three dimensional structures such as lateral stacking of hexagonal tubules, and final packing of the molecules in solution (concentration effects) to produce liquids, creams, solids, etc. Mammalian systems have natural degradative pathways for the rapid metabolism of most

lipid raw materials. However, the release of drug to a biological system will be controlled at least as much by these structural features as by simple natural degradative mechanisms.

Lipophilic Derivatives and Prodrugs

Lipophilic derivatives and prodrugs are a prudent tactic to alter the normal interaction of drug compounds with cells and cellular barriers. The type of modification desired may be a permanent one if the drug compound maintains its activity following conjugation, or a reversible type subject to biological cleavage. A variety of strategies for chemical coupling of lipids to drugs can be developed to produce the desired modified product (20). Briefly, nonreversible reaction approaches include conjugation to drugs with amine residues either via glutaraldehyde, lipid anhydrides or halides, or succinimidyl derivatives of the fatty acyl chain via carbodiimide activation. Nonreversible conjugations have also been accomplished via carbodiimide-activated carboxyl moieties of drugs reacted with amine containing lipids. Permanent conjugation to phenolic residues of drugs can be accomplished with diazo derivative of lipids bearing available amines. This approach has been successfully employed to prepare lipophilic derivatives of peptides containing tyrosine residues. Lipid conjugation reactions have also taken advantage of available sulfhydryl groups on drugs, particularly for modification of antibodies. On the other hand, bioreversible conjugates have been made via use of the Schiff base reaction to couple an aldehyde-bearing lipid to amines present on the drug. It is possible to convert the

hydroxyl groups of more abundant glycolipids to the corresponding aldehydes using periodate. An extension beyond the Schiff base reaction is the Mannich base condensation, which introduces a nucleophilic reactant such as an enolate anion or amide to the reaction between the aldehyde and amine. In these reactions the amine component is generally a lipophilic primary or secondary amine. Extensive literature is available on the production and biological activities of lipophilic *N*-Mannich base derivatives and stabilized α -acycloalkyl forms. The effect of lipophilic derivatized drugs given by various administration routes has been discussed in detail in several reviews (47–50).

Permeation Enhancers

There are a number of excellent reviews on the requirements for enhancing drug permeability across lipophilic biological barriers, with particular reference to the importance of the lipophilic properties of formulations (51–55). A listing of some penetration enhancing lipids can be found in Table 3. Administration sites include buccal, oral, nasal, ocular, transdermal, rectal, and pulmonary.

Vehicles for Dispersion

There is fairly extensive use of lipid materials in oral liquid dose forms strictly as vehicles. Primary applications have been as surfactants to promote drug suspension or dissolution (fatty glycols and fatty acids), as flavoring agents (natural or synthetic oils), and as thickening agents (hydrogenated oils). Aspects of

Table 3 Lipid permeation enhancers

Category	Compounds
Ionic lipids	Lauryl sulfate, dodecyl-2-pyrrolidone, <i>N</i> -dodecyl azacycloheptan-2-one (Azone), <i>N</i> -dodecyl- <i>N,N</i> -dimethyl betaine, calcium dodecylbenzene sulfonate, dioctyl sodium sulfosuccinate, dodecyl <i>N,N</i> -dimethylamino (acetate or propionate), and cetyltrimethylammonium bromide
Steroid and steroid esters	Cholate, deoxycholate, taurocholate, glycocholate, taurodeoxycholate, sodium taurodihydrofusidate, and cholesterol esters
Fatty-acids/fatty-acid esters/fatty alcohols	Oleic acid, lauric acid, capric acid, heptanoic acid, stearic acid, palmitoleic acid, palmitelaidic acid, octadecanoic acid, sucrose laurate, and isopropyl myristate
Phospholipids	Phosphatidylcholines, lysophosphatidylcholine, monooleoyl phosphatidylethanolamine
Oils	Monoolein, cocoa butter, cardamom oil, tricaprylin, mineral oil, terpenes, and terpenoids

pharmaceutical oral suspensions have been discussed in greater depth (56). Solution based-lipid vehicles have been applied in softgel applications, the primary category being oils that are compatible with gelatins and that have had applications as both lubricants for processing of the gelatin sheets and as drug vehicles for liquid fill operations into the softgel. High lipid concentrations may allow for higher ethanol content in softgel fills (57).

Lipids may also be used to create solutions for injectable products, particularly intravenous preparations. Fatty acids, fatty glycols, and fatty alcohols may be used to enhance the dissolution of certain insoluble drugs, act as preservatives, or function as active agents as demonstrated by Scleromate injection (Glenwood, Tena-fly, NJ), a mixture of fatty acid salts derived from cod liver oil. As another example, benzyl alcohol preservative has been useful in formulations for water insoluble drugs such as etoposide (VePesid[®], Bristol-Meyers Squibb, Princeton, NJ) and is a primary active agent in Zilactin gel (Zila, Phoenix AZ). Polyoxyethylated fatty-acid derivative has been used in the dissolution of phytonadione, a lipid-soluble vitamin (AquaMEPHYTON, Merck, Sharp & Dohme, Rahway, NJ) for subcutaneous or intramuscular injection. Injectable amphotericin B is solubilized with sodium desoxycholate in Fungizone (Bristol-Meyers-Squibb, Princeton, NJ). Polyoxyethylated or PEGylated castor oils are also used in dissolution of injectable drugs such as cyclosporine (Sandimmune, Novartis/Sandoz, East Hanover, NJ), paclitaxel, and teniposide (Taxol, and Vumon, Bristol-Myers Squibb) and miconazole (Monistat, Janssen Pharmaceutica, Piscataway, NJ). Clear colloidal dispersions are also possible using a wide variety of phospholipids, cholesterol esters, and tocopherol esters (13, 18).

Solid- and Liquid-Crystalline Suspensions, Creams, and Gels

Suspensions and creams are most often developed for aqueous insoluble drugs, as typified by ophthalmic and otic preparations of corticosteroids. In suspensions such as Cortisporin or Pediotic (Glaxo Wellcome, Research Triangle, NC), components such as cetyl alcohol, glyceryl monostearate, mineral oil, and propylene glycol are commonly used to effect a homogeneous suspension of drug particles.

The creation of fine suspensions may also be necessary to administer a highly insoluble product by parenteral injection. In these instances lipids may be used as either wetting agents or suspension vehicles (58). Lecithin (phosphatidylcholine) is a suitable agent for wetting or

suspending of drug particles in either aqueous or nonaqueous solutions. This common formulation additive is used for injectable long-acting IM suspensions of penicillin (e.g., Bicillin L-A[®], Wyeth-Ayerst, Philadelphia, PA) for the bronchodilator inhalation aerosol, Atrovent[®] (Boehringer Ingelheim, Ridgefield, CT), and for the otic suspension Cipro HC (Bayer, Germany). Naturally derived and synthetic lecithins, in mixtures with neutral lipids, also serve as the active ingredient in lung surfactants products such as Exosurf (Glaxo Wellcome), Survanta (Ross, Columbus OH), and Infasurf (Forest Labs, St. Louis, MO).

Lipid materials are used extensively as vehicles in topical creams, ointments, gels, and lotions, and usually serve as the base material for many such preparations. These formulations are principally presented as emulsions and may contain fatty acids, fatty-acid salts, fatty alcohols, petroleum based and natural oils, waxes, fatty glycols, lanolin, and other hydrophobic surfactants. Such emulsions are common in dermal topicals, for which the list of products is too numerous to elaborate. Some of these ingredients also are present as vehicles in suppositories such as semisynthetic glycerides existing in Nembutal (Abbott Laboratories, North Chicago, IL), hydrogenated vegetable oil as found in Dulcolax (Novartis Consumer Health), and glycerides of fatty acids or oils that can be found in vaginal suppositories such as Prostin E2 (Pharmacia and Upjohn, Kalamazoo, MI) and Crinone Gel (Wyeth-Ayerst). Mineral oil is frequently present in transdermal products such as Catapres-TTS (Boehringer Ingelheim) and Estraderm (Novartis Pharmaceuticals Corp). In addition, numerous ocular or topical ointments, such as Tobradex (Alcon Labs, Fort Worth, TX) and Nitro-Bid (Hoechst Marion Roussel, Kansas City, MO), use white petrolatum and mineral oil as a base. Short-chain triglycerides such as triacetin can be found in products such as Prepidil Gel (Pharmacia-Upjohn, Kalamazoo MI), a cervically administered prostaglandin.

Oil-in-water emulsions have also been applied for intravenous use. Commercial parenteral emulsions include Dizac (Schein, Florham Park, NJ) and Diprivan (Zeneca Pharmaceuticals, Wilmington, DE). Many commercial or experimental parenteral products have been based on vegetable oil (most often soybean, safflower, or cottonseed) stabilized with phosphatides and monoglycerides, which nicely match the hydrophile-lipophile balance (HLB) requirements of those oils ($\approx 6-7$). Further prospects for expanded nontoxic parenteral emulsions may come with use of other phosphatide-based surfactants with high HLB values (24, 59, 60). A number of excellent reviews and articles on the application of parenteral

emulsions for drug delivery have been written (61–65). Drug delivery from oil/phosphatide emulsions stems from earlier development and marketing of intravenous nutrient emulsion products such as Intralipid (KabiVitrum, Clayton, NC) and Aminosyn II, (Abbott Laboratories), which are sterile and nontoxic. The development of these emulsions as well as distribution profiles of these and similar emulsion compositions have been studied (63, 64, 66–68). A cursory scan of the literature on parenteral oil emulsion formulations will obtain studies on amphotericin B, prostaglandin E1, halothane, pregnanolone, paclitaxel, perilla ketone, penclomedine, F-octylbromide, flurbiprofen axetil (Lipfen), lasalocid, lignin, podophyllotoxin, tacrolimus, doxorubicin, epirubicin, menatetrenone, chlorpheniramine maleate, naproxin, cyclosporin A, propranolol, testosterone, benzocaine, phenylazoaniline, palmitoylrhizoxin, pilocarpine, diazepam, and various peptide and proteins for vaccine delivery.

Liposomal Dosage Forms

Extensive studies on liposomes date back to the 1960s. Many good comprehensive review references exist on compositions and manufacturing of liposomes (18, 23, 24, 69–73) including the article “Liposomes as Pharmaceutical Dosage Forms” in this volume. The earliest commercial liposomal formulations were developed for veterinary application (Novasome, IGI, Vineland, NJ) or over-the-counter cosmetic creams promoted for improved hydration (L’Oreal, Paris and Dior, Paris). More recently, parenteral liposome formulations of amphotericin B, doxorubicin, and daunorubicin have been approved and marketed (ABELCET, Elan, the Liposome Co., Inc, Princeton, NJ; AmBisome and DaunoXome, Nexstar/Fujisawa, Deerfield Park, IL; Amphotec and Doxil, Sequus/Alza, Menlo Park, CA), with others on the horizon for applications in photodynamic therapy (74). Although the vast majority of liposome preparations are constructed from phospholipids, other nonphospholipid materials can be used either alone or in mixtures to form bilayer arrays. One such example is Amphotec, which utilizes sodium cholesteryl sulfate as the primary lipid. Other liposome forming materials may include but are not limited to fatty-acid compositions, ionized fatty acids, or fatty acyl amino acids, longchain fatty alcohols plus surfactants, ionized lysophospholipids or combinations, nonionic or ionic surfactants and amphiphiles, alkyl maltosides, α -tocopherol esters, cholesterol esters, polyoxyethylene alkyl ethers, sorbitan alkyl esters, and polymerized phospholipid compositions (20).

Low Density Lipoprotein Carriers

Lipoproteins are naturally occurring particulate emulsion carriers for the transport of cholesterol and other lipids such as triglycerides in the blood. Because low-density lipoprotein (LDL) particle clearance is receptor mediated, they have been proposed as drug carriers for targeting applications, specifically for targeting of cytotoxic agents to tumor cells, delivery of antiviral agents to parenchymal liver cells, targeting of immunomodulators, antiviral and antiparasitic drugs to Kupffer and endothelial cells, and as gene vectors (75–78).

Solid Dosage Forms

The main use of lipids in solid form has been for oral tableting applications. Fatty-acid salts such as magnesium and calcium stearates, and various waxes and glycerides are most often used as conditioners and binders during compaction and provide more even, controlled, or slower disintegration of the tablet once administered. Extensive literature is available in which these materials are discussed in context of the preparation of oral tablets or capsules (79–81). The use of lipids for solid-implant formulations has also been investigated. Materials such as cholesterol, and high-melting-point fatty-acids, fatty anhydrides, and glycerides have been utilized in compressed implants to prolong systemic delivery of drugs (82, 83). Lipids are also well suited for suppository and vaginal insert formulations.

Safety of Lipid Products

The safety of a lipid product will in part be a reflection of 1) the purity of the compounds administered; 2) biological toxicity of the basic chemical ingredients; and 3) reactions to structural presentations of the lipid. Noncompendial lipid materials will necessitate significant toxicology testing.

Contaminants and impurities

Sensitive analytical procedures will be required to distinguish contaminants from lipid peaks within the preparation. By-products may be present from the synthetic processes used to produce the lipids or if copurified from the natural source. For example, common impurities in synthetic diacyl chain lipids are the monoacyl forms, which are generally more toxic to biological systems. Endotoxins and pyrogens either may be detectable in a lipid preparation (23, 84) or difficult to detect due to the lipids shielding against the analytical reagents (85).

Immune reactivity

Consideration should be given to immune reactivities when administering lipids to mammalian systems. Oils are well known for their adjuvancy; different oils will produce varying levels of reactivity (86). Biological responses such as leukocyte attraction, encysting of the oil, and edema reactions vary in severity simply as a function of the chemical nature or purity of the oil itself. Importantly, most lipids, including normal endogenous compounds possess antigenic potential to varying degrees (87). These possible reactivities should be monitored as part of the overall clinical design.

Conformational considerations

There may be biological sensitivities to the conformational presentation and sizing of the lipid formulation. For example the ability of antibodies to distinguish between lamellar organizing lipids and hexagonal-phase lipids are known and may form the basis for certain types of autoimmune dysfunction (88). Biological factors such as reticuloendothelial cell recognition of particles provide further impetus for control of the particle size and stability.

LAMINAR AIRFLOW EQUIPMENT: APPLICATIONS AND OPERATION

Gregory F. Peters

Lab Safety Corporation, Des Plaines, Illinois, U.S.A.

INTRODUCTION

The number and complexity of pharmaceutical manufacturing and compounding processes requiring protection from airborne contaminants has increased substantially in recent years. Because pathogenic viable and nonviable contamination may be readily introduced into a patient along with a therapeutic parenteral drug, the sterility and purity of parenterals must be controlled in the manufacture and assured in the compounding of these products. Laminar airflow (LAF) equipment is widely used as an engineering control in aseptic processing to provide a production environment free of airborne and resulting surface contamination by microorganisms, pyrogenic and drug residues, and other materials that present a risk of intravascular infection, pyrogenic response, or occlusion of the peripheral vasculature. With the growth of the small- and intermediate-size generic drug manufacturing, drug repackaging, and diverse hospital pharmacy and home health care IV admixtures, compounding industries, clean space design and management has become the direct responsibility of an increasing number of middle- and line-management personnel. As such, a working knowledge of LAF theory, aseptic processing, and clean space management is integral to the conceptualization, construction, and operation of a safe and effective clean space, and an important consideration in the selection or retention of the clean space manager and operative personnel.

CONTAMINATION CONTROL

All manufactured products are vulnerable to contamination by a myriad of aerosolized contaminants, including microorganisms, pyrogenic dust, ash, pollen, smoke, hydrocarbons, and other chemicals that are omnipresent in the environment (Fig. 1). Because of the potential dangers to the patient resulting from a parenteral product containing even minute quantities of these contaminants, exceptional measures are required to exclude them from the finished product. Careful planning is essential

in preventing contamination of the environment leading to occupational exposure of personnel to hazardous substances, which are routinely manipulated in pharmacy operations. The primary objective of the aseptic process is control and elimination of viable contaminants. These contaminants are numerous and varied, normally consisting of bacteria, fungi, and viruses. Viruses are usually short-lived upon exposure to air, and require host systems to remain viable and reproduce; they are generally not of direct concern, except in excluding their vector, or transport mechanism. Aseptic processes are designed to exclude bacteria and fungi as well as their spore forms and breakdown products. Many of these contaminants are naturally airborne and occur commonly in the atmosphere. However, the contamination of greatest concern in aseptic processing is the endogenous microbiologic material generated by the operative personnel and others involved in the manipulation of parenteral products. This type of contamination is easily aerosolized and introduced into air currents by normal "shedding" of endogenous microbiota, and by mechanical means as microscopic droplets of sputum, produced by talking, laughing, or sneezing. Endogenous contamination is generated in enormous quantities on the skin^a (1) and may be deposited on the surfaces of containers, equipment, gowns, and materials introduced into the aseptic work field during the course of manipulations.

Waterborne contaminants may also be introduced by contaminated cleaning agents or poor cleaning and sanitizing techniques. All types of gross microbiologic contamination are found on work surfaces, gloves, and compounding materials following contact with contaminated objects. Pyrogenic and nonpyrogenic dust must also be excluded from parenteral products. Even minute quantities of this material may cause acute inflammation or abscess at the injection site, and induce a life-threatening pyrogenic response. In addition, evidence of long term dangers of fiber emboli in producing pulmonary and

^aThe average adult human sheds 25,000–50,000 *Staphylococcus epidermidis* particles per minute; one person in five is a carrier and active producer of *Staphylococcus aureus*, the organism responsible for toxic shock syndrome, a bacteremia fatal in 50–90% of reported cases.

cerebral granulomas, stenosis, and occlusion of micro-circulation, as well as clouded vision, and neurological sequelae in patients receiving particulate-contaminated intravenous admixtures has emerged (2, 3). Additionally, drug product residues remaining in the aseptic processing field as a result of improper line-clearance are a threat to the patient for whom they are not intended.

History

LAF is an “offshoot technology” stemming from development of the high efficiency particulate air (HEPA) filter, spearheaded by the U.S. Army Chemical Corps, Naval Research Laboratories, and the Atomic Energy Commission in the 1940s and 1950s. Known as an absolute filter, the HEPA filter was further developed by the nuclear industry to provide fail-safe removal of extremely hazardous microscopic airborne particulates^b at nuclear facilities. In the late 1950s, a proliferation of laminar flow clean benches (LFCBs), incorporating a HEPA filter, made it possible for the hospital pharmacy to achieve a small, but exclusive compounding environment of sterile air and sanitized, bacteriostatic worksurfaces in

^b99.97% of particulates smaller and larger than 0.3 microns.

which to prepare small numbers of individual, patient-specific sterile products.

On a broader scale, pharmaceutical manufacturers were beginning to utilize absolute filtration as a primary engineering control in the maintenance of large, carefully controlled clean spaces in the batch production of quality-controlled parenteral products. In this application, LAF was supplied directly to production lines and extended critical worksurfaces within defined, nonturbulent entrance and exit planes as parallel or “columnated” airflow (misnamed “laminar flow”).^c This highly controlled laminar airstream was supplied to the critical worksurface, in addition to conventionally supplied turbulent airflow to the general space, provided through terminal diffusers for filtration of the balance of room air. In this manner, the “stepped” control of all critical, as well as support areas was achieved.

In the mid-1970s, increased control of manufacturing process air quality became possible with the refinement of LAF clean space design, the growing body of

^cLaminar flow is defined as a fluid stream having discernible differentiations (laminations or layers) of velocity, pressure, temperature, or other characteristic, whereas parallel flow is uniform throughout its vertical, horizontal and longitudinal extent.

historical process quality data, the refinement of statistical process controls (SPCs), and the emergence of industry operating standards (4). In 1979, concern for the safety of pharmacy personnel compounding anti-neoplastic drugs in LFCBs was expressed, following studies that clearly identified the potential health risks to these personnel (5). The introduction and widespread use of the Class II laminar flow biological safety cabinet (BSC) by oncology/hematology pharmacy occurred in the late 1970s, and was almost universal by the end of the 1980s. Additional studies conducted in the late 1990s clearly indicated that, in spite of pharmacy-wide implementation of Class II BSC containment technology, the same potential health risks identified in 1979 continued to exist in the workplace (6). The swift, anecdotal response in some segments of the pharmacy industry was to strongly recommend immediate retrofit of the Class II design with the Class III BSC, or Barrier Isolator (sometimes referred to as a “barrier hood”) in the glovebox or half-suit configuration, as an alternative to “open” Class II units used by pharmacy in a manner that had ostensibly failed to protect workers and the environment. This recommendation, however, was not based upon adequate and careful engineering failure analysis (FA) of the Class II design as implemented in pharmacy operations, by which the Practice might rationally evaluate and address the reasons for such failure. Neither, as of this writing, have any systematic, scientifically based feasibility studies, validation and monitoring protocols, or operating specifications leading to proper, corrective retrofit with the Class III or barrier isolator designs been developed as a corollary to such FA. (It should be noted that not all “barrier isolators” or “gloveboxes” are Class III BSCs.) These steps are absolutely essential in preventing a repeat failure of any type of BSC in the engineering control of hazardous substances manipulated by pharmacy personnel, and the resulting characterization of the IV pharmacy as a serious occupational risk environment.

THE HEPA FILTER

The essential element common to all LAF equipment is the HEPA filter.

Construction

The HEPA filter is normally constructed of borosilicate microfibers, formed into a flat sheet by a process similar to papermaking (Fig. 2). This sheet is pleated to increase the

Fig. 2 HEPA filter cross-section showing pleated construction. (Courtesy of the Baker Company, Sanford, Maine.)

overall filtration surface area, in order to minimize the static pressure drop across the filter to a predetermined value^d at a given airflow specification. The pleats are separated by serrated aluminum baffles or stitched fabric ribbons, which direct airflow through the filter. This combination of pleated sheets and baffles facilitates maximum exposure of the upstream filtration area to the airstream and is referred to as the filtration medium. It is constructed in a predetermined size, and installed into an outer frame made of fire-rated particle board, aluminum, or stainless steel. The frame-media junctions are permanently glued or “pot-sealed” to ensure a leakproof bond. The frame is fitted with a continuous, closed-cell neoprene gasket or other suitable occlusive seal to provide a gas-tight installation of the filter into the air handling system.

Filtration Efficiency

Refinement of HEPA filter manufacturing and testing technology and development of the ultra low particulate air (ULPA) filter, have led to an increase of absolute

^dNormally 0.50–1.2 inches. water column (WC) or water gauge (WG).

filtration retention efficiency of greater than two orders of magnitude above 99.97%. HEPA filtration efficiencies range from a minimum of 99.97 to 99.99%, with ULPA efficiencies above 99.9999% for particulates larger and smaller than 0.3 μm in diameter (Fig. 3). (HEPA filters used in pharmaceutical and pharmacy-compounding applications rarely exceed 99.99%.) Expressed another way, the HEPA filter is capable of trapping and retaining 999,700–999,900 of every 1,000,000 particles smaller and larger than 0.3 μm in diameter.

Filtration Mechanisms

The three principal filtration mechanisms (Fig. 4) by which aerosols are collected on the HEPA filtration medium are:

- Inertial impaction, where particle inertia causes it to leave the flow streamlines and impact on the fiber;
- Interception, a screening effect dependent upon particle fiber-size relationships; and
- Diffusion, a Brownian motion diffusion of very small particles due to molecular bombardment (7).

Other filtration mechanisms, such as sedimentation and electrostatic attraction, provide some degree of aerosol collection, however most particulates are removed from the airstream by the above methods.

Shipment, Storage, and Handling

The HEPA filter is extremely fragile and should be shipped, stored, and handled in the same manner as delicate instrumentation. Personnel responsible for receiving and handling HEPA filters should receive training in proper handling technique. All incoming HEPA filters should be visually inspected for apparent damage due to

mishandling, and all damage described in detail on the shipping documentation prior to acceptance.

Filtration Performance Certification

Individual HEPA filter efficiencies are established by an exacting challenge of the filter frame and medium, usually incorporating a “cold-boil,” polydisperse aerosol of dioctylphthalate (DOP) or equivalent (8), which is introduced into the upstream plenum-side of the filter in a manner that ensures even distribution of the test aerosol behind the filter, at its rated airflow.

Following verification of acceptable airflow velocities, expressed by the manufacturer in linear feet per minute (LFPM) or meters per second (m/s), leakage is determined by measuring the penetration of the test aerosol through the filter as a percentage of the upstream plenum aerosol concentration, using an aerosol photometer (4) or optical particle counter (9) to carefully scan the entire filter media face and frame. Penetration of the test aerosol at or above 0.01% of the upstream concentration is considered a leak requiring repair. Leakage should be repaired only with room temperature-vulcanizing (RTV) silicone caulk, which is easily applied, and exhibits long term stability and resistance to deformation. Repairs to the filtration medium should be made in the manner specified in the literature (10). Individual repair “patches” should not exceed 1.5 in. in length or width, nor should the sum total of all repairs exceed 3% of the total area of the filter face. During operation and at all times no object, drug residue, or debris should be permitted to come into contact with the HEPA filter.

LAF AS A BARRIER TECHNIQUE

LAF has long been the primary method of controlling airborne contamination in the aseptic processing of pharmaceutical and pharmacy products. Also known as nonturbulent, or unidirectional airflow, LAF is generally defined as “HEPA-filtered air having parallel streamlines, flowing in a single pass and direction through a clean zone” (4). LAF is technically defined as fluid flow without macroscopic fluctuations, which generally occur when the Reynolds number^e is less than 2000. Industry standards require that 80% or more of the total airflow exhibit this characteristic, in order to meet the

Fig. 3 Theoretical HEPA filter-collection efficiency. (Courtesy of the Baker Company, Sanford, Maine.)

^eThe “Reynolds number” is the ratio of inertial to viscous forces in a pipe or duct.

Fig. 4 Air filtration theory particle-collection mechanisms. (Courtesy of the Baker Company, Sanford, Maine.)

definition of LAF (11). LAF is necessary to maintain the most stringent air cleanliness classes^f (4) in the production of “first air”^g at the critical worksurface of the LFCB and BSC, and in operational cleanrooms (4,11). It is important to note that the terms “laminar airflow” and “Class 100” are not interchangeable; LAF first air incorporating properly validated HEPA filtration produces air cleanliness of approximately Class 1, nearly two orders of magnitude cleaner than Class 100. Class 100 nonlaminar airflow does not constitute first air within a critical work zone, and should not be substituted in applications requiring or designating LAF.

Conventional Airflow

Conventional airflow (also known as turbulent, or non-unidirectional airflow) incorporates HEPA filters, located in-duct, or as room terminal filtration modules (TFMs; Fig. 5). Often confused with LAF, conventional airflow does not meet that definition because it allows multiple-pass circulating characteristics or a nonparallel airflow direction, or both. This type of airflow is incapable of producing first air, and is normally used as secondary or “buffer” filtration in treating a processing or compounding space that contains laminar airflow devices (LAFDs) to maintain primary critical work surface conditions, or in treating other processing or

support areas about which a definitive air cleanliness statement must be made. Properly designed, a conventional airflow system is effective in maintaining the less-stringent air cleanliness classes^f in operational cleanrooms (4, 11).

Advantages

When used properly by trained personnel, employing adequate process controls, the LAF environment provides a reliable barrier to measurable airborne viable and nonviable, solid particulate contamination, which may defeat the aseptic process. LFCBs, BSCs, and heating, ventilation, and air conditioning (HVAC) installations are easily validated. These systems normally continue in operation with little or no variation in output quality for long periods of time, and are easily maintained and tested.

Limitations

Any discussion of LAF equipment must include consideration of aseptic technique and the aseptic process as a whole. Often relied upon as an infallible process support, LAF is in fact a fragile, protective envelope of slow-moving, aerosol-free air^h (4) the effect of which is easily disrupted and defeated by improper placement of processing materials, poor manufacturing and personnel practices, inadequate aseptic technique, or failure to maintain the HVAC components. Although the laminar slip stream itself is free of particulates, it does not eliminate particulates or other surface contaminants present in the aseptic field, or contamination introduced into the aseptic field on the surfaces of improperly prepared

^f“... Most stringent air cleanliness classes ...” are defined as class 10–100, (F.S. 209e); Classes C, D, and E (British Standard 5295); Classes 4–5 (EN ISO); Grades A–B (EC). “...less stringent air cleanliness classes...” are defined as Class 1,000–100,000 (F.S. 209e); Classes F through K (B.S. 5295); Classes 6–8 (EN ISO); Grades C–D (EC).

^g“First air” is uninterrupted air issuing directly from a HEPA filter in a laminar-airflow environment.

^hAirflow velocity exiting an unobstructed workstation should be maintained at 90 LFPM average with a uniformity within $\pm 20\%$ across the entire area of the exit.

Fig. 5 (A) The self-contained terminal HEPA filtration module (TFM). (B) Arrangement of TFMs in the T-Bar ceiling in a conventional-flow application. (Courtesy of American Air Filter, Inc., Louisville, Kentucky.)

processing materials, and their manipulation and storage within the aseptic environment. Neither is LAF a substitute for proper manipulative and aseptic technique. Excessive confidence in any LAF system should not lead to the neglect of proper precleaning and staging of processing materials, personnel selection, training, and validationⁱ (12); effective routine housekeeping and maintenance procedures (13); and aseptic process monitoring and auditing methods.^j This may result in a breakdown of the process and a compromise of product integrity. In addition,

ⁱ1) Personnel selection and screening criteria; 2) a formalized training program to include a period of supervised manufacturing or clinical experience culminating in a recommendation for validation by the supervisor; 3) a personnel validation method, including a written exam with a required passing grade, and a practical assessment of aseptic technique, utilizing sterile microbiologic growth media in a process simulation incorporating all processing steps encountered by the candidate during the actual processing operation.

^jQuality assurance (QA) testing and recertification of LAF systems and other engineering controls, which support the aseptic process (process auditing), irrespective of quality control, or procedures to demonstrate conformance with product specifications of identity, purity, sterility, and apyrogenicity (product auditing).

the use of improper manipulative technique in BSCs and containment systems may result in a compromise of the waste-stream, resulting in cumulative contamination of operative personnel and the environment.

Operating procedures

Although the design of each type of LAFD dictates certain specific operating procedures, several general principles apply to all LAFDs (9).

Cleaning and preparation: LFCB: The LFCB should be allowed to run for at least 30 min before the commencement of aseptic operations. All work-zone accessible surfaces, with the exception of the filter-protective screen, should be cleaned and sanitized by application and recovery of a low-residuing, water-base disinfectant cleanser (household bleach or other hypochlorite solutions should not be used at any time on stainless steel surfaces), followed by application of 70% ethyl or isopropyl alcohol sprayed evenly length-wise across the work surface from the back of the cabinet to the front, and allowed to dry (14). (The combination of a water-base disinfectant cleanser with alcohol provides

both the broadest antimicrobial action and widest range of surfactant and solubility factors for recovery of surface residues during the cleaning process.)

BSC: The BSC should operate continuously to ensure containment of hazardous substances. All work-zone interior surfaces with the exception of the HEPA filter-protective screen should be cleaned and sanitized in the manner of the LFCB in the proper order to ensure protection of operator's garb from contaminants and cleaning residues during the cleaning process. This will also prevent transfer of drug residues to the general environment (14).

Staging

After drying of the work surface, operations in the LAFD should begin with staging of all working materials for introduction into the aseptic work area (14). This should include:

- assembly of required working materials: drug components, syringes and sterile fluid pathways, diluents, dispensing and venting devices, wipes, final containers, etc.
- preparation, in a Class 100,000 environment (4), of all working materials to go into the aseptic field by sanitizing with 70% ethyl or isopropyl alcohol spray, wiping all containers, careful removal of gross contamination and filth from any container that does not have an outer wrapper, removal of inner containers from their outer wrappers, and placement of all materials on a sanitized, stainless steel surface. This is preferably a cart or tray at a close proximity to the LAFD for direct loading of materials into the aseptic work zone.

Materials such as paper, labels, writing implements, etc., should not be placed into the work zone.

Aseptic manipulation

Prior to introduction of the working materials into the LAFD, the gloved hands of the operator should be thoroughly washed and rinsed to remove dry lubricants, sanitized by spraying with 70% alcohol, and allowed to dry in the laminar airstream. The working materials may then be transferred to the work zone, and aseptic manipulations begun. The operator's hands should be slowly inserted into, and removed from the laminar airstream, in order to minimize backwash and cross-stream contamination of the work zone. Working materials should be arranged in such a way that work progresses laterally, from right to left or left to right, so that non-interrupted first air is continuously supplied to the critical surfaces of all working materials at all

times. If the operator must leave the work zone area, his or her gloved hands should be resanitized with 70% ethyl or isopropyl alcohol prior to reentering the work zone. This practice takes little time and minimizes contamination of the work zone by endogenous and residual environmental flora. An alcohol-spray bottle or other suitable dispenser should be provided close to the work zone entrance for this purpose, with the alcohol filtered and the dispenser sanitized each time the dispenser is refilled. Good aseptic technique is essential to retain the sterility of compounded products, and properly fitting surgeon's gloves, mask, laboratory coat (or arm barrier), and hair cover are recommended for all pharmacy operators working in the LAFD^a (1, 14).

LFCB

The oldest and most basic LAFD is the LFCB, universally referred to as a "hood"—an enclosed work area with its own HEPA-filtered air supply (Fig. 6). It provides only product protection by capturing room air, passing it through a HEPA filter, and directing the filtered air horizontally or vertically uniformly across the work surface toward the operator at a constant speed.

Limitations

The LFCB should not be used in operations requiring manipulation of cytotoxic, radioactive, microbiologic, or other hazardous materials, which may become aerosolized and aspirated by the operator. Reconstitution and manipulation of antineoplastics and vesicants, mass reconstitution of antibiotics, antivirals, vaccine formulation, and similar manipulations should be done in a laminar flow BSC.

Fig. 6 The LFCB airflow profile. (Courtesy of the Baker Company, Sanford, Maine.)

Placement of materials in the work zone

Working materials placed into the LFCB should be positioned a minimum of three object-diameters in from the open end of the unit when the object is exposed to the laminar airstream on all sides, and a minimum of six diameters in from the open end when working at either end of the unit or when the object is exposed to the laminar airstream on only one side (14). This general method counteracts backwash contamination, which may compromise the aseptic field. The introduction of any large object (automated, high speed compounding devices, water baths, carboys, etc.), obstruction, or complicated process into the laminar airstream may likewise induce backwash contamination, and should be validated to maintain cohesion of the airstream and exclude both backwash and cross-stream contamination during the process. This may be accomplished by the use of visual tracers, such as smoke sticks or other smoke-producing devices, to introduce quantities of smoke both upstream of the critical worksurface and at the open end of the unit during a process validation or qualification run for visual observation of airstream behavior. Work should take place not less than 6 in. in from the open end of the work surface. Although engineering improvements in the laminar airstream recovery have been made, the laminar airstream is slow-moving,^k and care should be exercised in the location, operation, and maintenance of this unit.

Location and performance testing

The LFCB should be located in an area free of ventilation or other air currents, steady or intermittent, which might hamper the laminar airstream by backwash effect.^l Performance testing of the LFCB by a qualified inspector is recommended at least every 6 months, and servicing or replacement of the unit prefilters every 60 days or less.

Applications

The LFCB is used in hospital, clinical, and home health care pharmacies to provide a sterile field in which to conduct aseptic manipulations in the compounding of large-volume parenterals (LVPs) in the form of IV admixtures, hyperalimentation, and small-volume parenterals (SVPs) in the form of piggybacks, syringes, or other parenteral products of less than 250 ml, and for general sterile manipulation of nonhazardous materials.

^kNormally 90 LFPM \pm 20% or as specified by the user.

^l“Backwash contamination” is the general term given to the reflux entry of unfiltered room air into the LAFD work zone.

In industry, the LFCB is used to conduct small batch sterile filling operations, in the general manipulation and isolation of nonhazardous materials, and in quality assurance/quality control (QA/QC) sterility testing.

Laminar Flow BSC

Pharmaceutical and clinical research in the past four decades has led to the development of drug products and other hazardous substances, the manufacture, handling, and compounding of which are considered hazardous to operative personnel in both the short and the long term (15). In addition to protection of the purity and sterility of the product, it is necessary to consider protection of personnel and the environment. The need to protect both the product and personnel has resulted in the adaptation and use of a variety of laminar flow BSCs in the manufacture and compounding of numerous biological, radioactive, cytotoxic, allergenic, and antibiotic drug products. It is necessary that proper containment and barrier techniques be followed in the preparation, operation, and cleanup of any BSC. Although both are considered to be LAFDs, a clear distinction between the LFCB and BSC should be made in the training of operative personnel. There should be no generalized “grouping” of BSCs and LFCBs as “hoods” requiring similar use and maintenance patterns; each type of LAFD has airflow patterns, containment characteristics, and operating requirements unique to its design (Fig. 7). Operative personnel must understand that the containment and barrier techniques used in the operation of the BSC are significant not only as protection against sudden, overt contamination, but more importantly, as barriers to traces of residual contamination to which constant exposure may present long term health risks (15,16). Current pharmacy practices and contamination control manipulative techniques have been shown to be inadequate to contain hazardous substances in all phases of compounding and administration, and a pharmacy-wide study and standardized, remedial training programs must be quickly developed and carried out to protect operative personnel (6, 17).

Classification

BSCs are divided into three classes. Class I and Class II are used for low to moderate risk agents, and Class III for high risk agents. The risk level serves as a guide for pharmaceutical manufacturing and pharmacy compounding operations based on a reasonable extrapolation from the personnel risk levels, containment models, and product/personnel protection factors encountered in

operations using the biological agents for which this type of equipment was originally designed.

The BSC in pharmacy operations

Although the BSC was not specifically designed for pharmaceutical manufacturing or pharmacy compounding operations, reasonable analogies in the management of hazardous aerosols may be made, justifying use of the BSC in such operations. Such was the case in 1979, following a comprehensive study (5) that determined that pharmacy and nursing personnel were experiencing occupational exposures to antineoplastic agents following their compounding in LFCBs and routine administration. As a prudent response to these findings, recommendations based upon such analogies by segments of the pharmacy community facilitated pharmacy-wide use of Class II BSCs. The Class II design was quickly implemented without attendant feasibility studies, validation and monitoring protocols, or standardized operating, cleaning, and line-clearance procedures, resulting in the installation and operation of this equipment with wide variation in its effectiveness from institution to institution.

Recent studies have indicated the unabated occupational exposure of pharmacy personnel to these substances, causing an inference of the inadequacy of the Class II system in controlling environmental contamination (6). These findings have again prompted vendors and segments of the pharmacy community to aggressively promote use of the Class III BSC, or barrier isolator, postulating that a so-called "closed system" would unfailingly prevent the transfer of hazardous agents to the environment, thus preventing personnel exposures. Pharmacy-wide promotion of a containment technology is

thus being repeated without the benefit of comprehensive engineering studies to both identify the reasons for any "failure" of the Class II system, and to provide standardized procedures to properly implement and operate the Class III system. It must be noted that Class II systems are completely effective in the management of particulate and aerosol contaminants in the microbiologic and toxicologic procedures for which they were originally designed. These contaminants include numerous dangerous agents, for which exacting, albeit decades-old manipulative and management techniques remain effective. No applications' failure of the Class II system has yet been reported by these industries, implying that it is improper use of this equipment and/or poor manipulative, product transfer, and cleaning techniques by pharmacy and nursing personnel, rather than any inherent design or applications' flaw in the Class II system, which would account for unabated occupational exposures (17). At this writing, insufficient evidence appears to exist supporting the remedial, pharmacy-wide retrofit of the Class II system with the Class III BSC, or barrier isolator. The pharmacy community should, rather than prematurely dispose of an effective and functional containment system for a more complex and expensive design, seek to identify and correct the cause(s) of such personnel exposures. A controlled study measuring the nature and magnitude of personnel exposures prior to, and following implementation of carefully designed and executed training exercises, containment procedures, and waste-streaming techniques should be carried out prior to any measures to retrofit these engineering controls.

Following any scientific determination of the inadequacy of the Class II technology in providing the necessary

Fig. 7 Airflow patterns in horizontal- and vertical-flow LFCBs and vertical-flow laminar flow BSC. (Courtesy of the Baker Company, Sanford, Maine.)

levels of operator and environmental protection, the Class III and barrier isolator systems should, without presumptions, be carefully evaluated for use in this application. Such evaluation should systematically encompass the full range of performance, operational, and maintenance factors, which bear upon gloveboxes or other closed systems, such as lowered productivity because of the cumbersome nature of gloves, half-suits, and reduction of dexterity; difficulty in effective cleaning, resulting in increased residual and cross-contamination of products; inferior product protection characteristics of turbulent Class 100 supply airflow; lowered throughput; increased compounding time and errors; and the manner in which these factors may inhibit the product protection capabilities of the Class III design.

Suitability

Prior to choosing a BSC for any pharmaceutical manufacturing or pharmacy compounding operation, all risks should be assessed by a qualified process engineer, safety officer, or industrial hygienist, ensuring that the equipment meets occupational safety as well as process requirements.

Class I BSC: The Class I BSC is an open containment unit suitable for work involving agents of low to moderate risk to the user and environment, where there is a need for containment but none for product protection or isolation. The Class I BSC provides protection to personnel using the cabinet by means of constant, controlled airflow into the work area and away from the operator, preventing the escape of aerosols through the front opening. It is of limited use in manufacturing and has no reported use in the current practice of pharmacy.

Class II BSC: The Class II BSC (Fig. 9) provides product, personnel, and environmental protection, and is the most common BSC employed in pharmaceutical manufacturing and pharmacy-compounding operations. The Class II BSC has several subclassifications, based upon cabinet ventilation design (18) (Table 1). The Class II BSC (Fig. 8), the most widely used by hospital and home-care pharmacies, features a front access opening

with carefully maintained inward airflow for replacement of air exhausted from the cabinet, a HEPA-filtered vertical laminar flow airstream within the entire work area, and HEPA-filtered exhaust air. The vertical laminar flow airstream and front access opening are common to all Class II cabinets, although LAF velocities and patterns, HEPA filter sizes and position, ventilation rates, and cabinet exhaust methods vary considerably in different designs (Fig. 7).

Class III BSC: The Class III BSC (Fig. 9) provides the highest level of personnel, product, and environmental protection from high-risk microbiologic and toxicologic agents. It is usually employed in pharmaceutical manufacturing operations involving weighing, diluting, and high volume aerosol generation of high-risk agents, as well as for handling contaminants that are slowly or rapidly vaporized. This type of laminar flow device affords the maximum containment and product protection barrier, and is used only in cases of extreme exposure hazard or product sensitivity.

The Class III BSC is a gas-tight enclosure, utilizing total air displacement ventilation that protects personnel from exposure to the products contained within the enclosure, the product from contaminants found in the ambient environment, and the environment from release of potentially hazardous substances. The Class III BSC is used where absolute containment of hazardous agents is required, and is normally configured with glove ports housing gas-tight, full length latex, neoprene, PVC, urethane, or laminated polymer gloves (19).

Operating procedure

In addition to cleaning all accessible work zone surfaces, the Class II BSC worksurface tray should be lifted up and back, and the area under the tray should be thoroughly cleaned with the same frequency as the other user-accessible worksurfaces; this is of particular importance in preventing the buildup of potentially harmful product residues. All materials used in cleaning and sanitizing should be treated as toxic waste, and disposed of in accordance with state and local

Table 1 BSC cabinet ventilation

(Type) Class II	Cabinet air characteristics	Air recirculated (%)

Type B1	70% Ducted to outdoors	30
Type B2	100% Ducted to outdoors	0

*

ordinances. Following complete drying of the work surface, operations may begin by staging all working materials for introduction into the aseptic work area. The working materials may then be transferred to the work zone, and aseptic manipulations begun. Work should be performed only on the work surface, taking care not to handle or store materials on or near the ventilation grilles. First air should be maintained at the critical surfaces of all working materials in the aseptic field; interference with the vertical flow of first air by passing anything over critical orifices or septa in the aseptic field must be prevented. Good aseptic technique is essential to retain the sterility of compounded products^m (14) and surgeon's gloves, mask, laboratory coat (or arm barrier), and hair cover are recommended for all pharmacy operators working in the BSC.ⁿ

Location

The location, operation, and maintenance of the BSC should be carefully planned. Similar to LFCB, the BSC should be located in an area free of steady or intermittent air currents, which might defeat the laminar airstream by a backwash effect^l. The BSC should be connected to an adequate power source, having the minimum possible current fluctuation. The effects of voltage variation on cabinet performance can be pronounced (Fig. 10A), causing a variation in intake and supply velocities sufficient to result in an unacceptable unit performance (Fig. 10B), thereby compromising personnel and product protection design features (Table 2). Performance testing of the BSC by a qualified inspector is recommended at least every 6 months and always after relocation of the unit. Appropriate surface decontamination is recommended prior to moving or refiltering the unit.^o

^mThe importance of good aseptic technique is occasionally deemphasized by personnel compounding cytotoxic and antibiotic agents in the BSC, based on the belief that these substances are themselves toxic or germicidal to any microbiologic contaminants. It should be noted that numerous microbiologic organisms remain viable and replicate in cytotoxic compounds, and that no antibiotic has a universal antimicrobial action. Proper aseptic technique is therefore mandated in all operations carried out in the LAF environment.

ⁿThese are basic barriers, proven to aid in the retention of gross endogenous contamination at close working proximity to the critical field, but as importantly, these barriers protect the operator from direct contact with potentially hazardous substances, and should be used in accordance with established guidelines (see "Regulatory Issues").

^oAlthough microbiologic decontamination of the BSC is not required, except as used in the manipulation of microbiologic agents, proper containment technique should be employed when refiltering or servicing these units.

Applications

The BSC is used in hospital, clinical, and home health care pharmacies to provide a sterile field in which to conduct aseptic manipulations in the compounding of LVPs, SVPs, antineoplastics, antibiotics, antivirals, and vaccines, the direct exposure to which may be hazardous to the operator and the environment. Most hospital and clinical pharmacy operations are currently carried out in a Class II(B3) BSC, which is vented to the outside by a dedicated, nonrecirculating HVAC exhaust, directly connected to the BSC.^p Although direct connection to an HVAC exhaust is not required for proper Operation of the Class II(a) BSC in the containment of biological aerosols, such direct connection is recommended in all pharmaceutical manufacturing or pharmacy-compounding applications. The Class I BSC is almost never used in pharmacy compounding operations, and the Class III BSC technology is currently being evaluated for use in pharmacy compounding following comprehensive evaluation of any Class II FA, and outcomes of feasibility studies of the Class III system in such operations.

In industry, the BSC is used to conduct small batch sterile-fill operations, manipulation (weighing and

^pCurrent guidelines may recommend use of the Class 11 Type B2 (total exhaust) BSC in certain manufacturing and compounding applications, but proper operation of this unit is difficult to maintain because of non-interlocked operation of separate BSC supply and in-house exhaust air-handling systems. B2s in the configurations currently available frequently develop a supply-exhaust flow imbalance, which may readily compromise product or personnel protection. Until a reliable system for direct interlock of the supply and exhaust air handlers is available that synchronizes the operation of the components, facilitating changes in operation by either air handler being proportionately matched by the other, use of the Class-11 Type B2 BSC is not recommended for pharmaceutical manufacturing and pharmacy compounding applications as a containment LAFD.

Fig. 8 Airflow patterns of the Class II(a) laminar flow BSC. (Courtesy of the Baker Company, Sanford, Maine.)

pouring), isolation of hazardous materials, and in QA/QC testing applications. All classes of BSC are encountered in pharmaceutical manufacturing operations for a wide variety of processing applications.

Terminal HEPA Filtration Module

The terminal HEPA filtration module (TFM) is a self-contained HEPA filter and plenum unit (Fig. 11), which may be used to provide laminar or conventional airflow⁴ to a clean space, or may be dedicated as a LAF workstation (20). The TFM is available with a 10 in. (optional 12 inch) collar for connection by a circular supply duct to a central air handling system (Fig. 5A) or as a free-standing, fully powered unit containing a motor

⁴Laminar-airflow room is defined as a cleanroom in which filtered air entering the room makes a single pass through the work area in a parallel-flow pattern, with a minimum of turbulent flow areas. Laminar-flow rooms must have HEPA filter coverage of at least 80% of the ceiling (as vertical flow), or one wall (as horizontal flow), producing a uniform and parallel airflow (net filter medium face area versus gross area = 0.80).

and blower. It is normally installed in a "T-bar" grid ceiling system, suspended by seismic restraints from the architectural ceiling or building supports (Fig. 5B), which constitutes the inner clean space ceiling. Permanently installed or modular air handling systems are available that provide treatment (heating, air conditioning, dehumidification, etc.) of recirculated and make-up air to the clean space. Self-powered TFMs do not provide supply air treatment, and care should be taken in installing this type of unit because of high noise level and heat output factors, which may fatigue operative personnel or adversely affect temperature-sensitive stored drug products.

The TFM may also be used to provide a Class 1–100 work surface of almost any size, and may be installed in the ceiling (vertical downflow), or in a wall (horizontal flow). Using this design, shrouded laminar flow Class 1–100 "first air" is provided directly to the critical worksurface in the same quantity and quality as by a LFCB. Outflow from the critical worksurface is used to treat the general space, in combination with additional room "buffer" HEPA filtration, thus

Fig. 9 Airflow patterns of the Class III laminar flow BSC. (Courtesy of the Baker Company, Sanford, Maine.)

providing both the highly-controlled critical work surface, and the less-controlled general room area. Several inexpensive concept designs are available to develop reliable work surfaces and buffer areas, which support both pharmacy and pharmaceutical manufacturing operations (20).

In-duct HEPA filtration

In this type of filtration the HEPA filter is placed within the supply duct system, providing Class 100 air from the point immediately downstream of the filter to the supply diffusers within the general clean space. This arrangement is used where a comparatively small volume of supply air is required for the clean space operation, when filter handling and disposal is critical (requiring remote “bag in/out” containment isolation or other special handling considerations), or where space

limitations prevent the installation of TFM. Induct HEPA filtration provides conventional airflow and is recommended as secondary or “buffer” filtration in clean spaces where critical work zones are treated using an LAFD. In-duct HEPA filtration is not recommended for LAF applications to provide required Class 1–100 conditions at critical work surfaces, where uninterrupted “first air” is necessary to achieve the highest levels of contamination control.

The plenum ceiling

The plenum ceiling is an arrangement of ductless terminal HEPA filter modules which, in a manner similar to TFM, are installed in a “T-bar” grid system. These filter modules are not connected directly to an air handling system by means of ducts. The uniform flow of air through all modules results rather from a

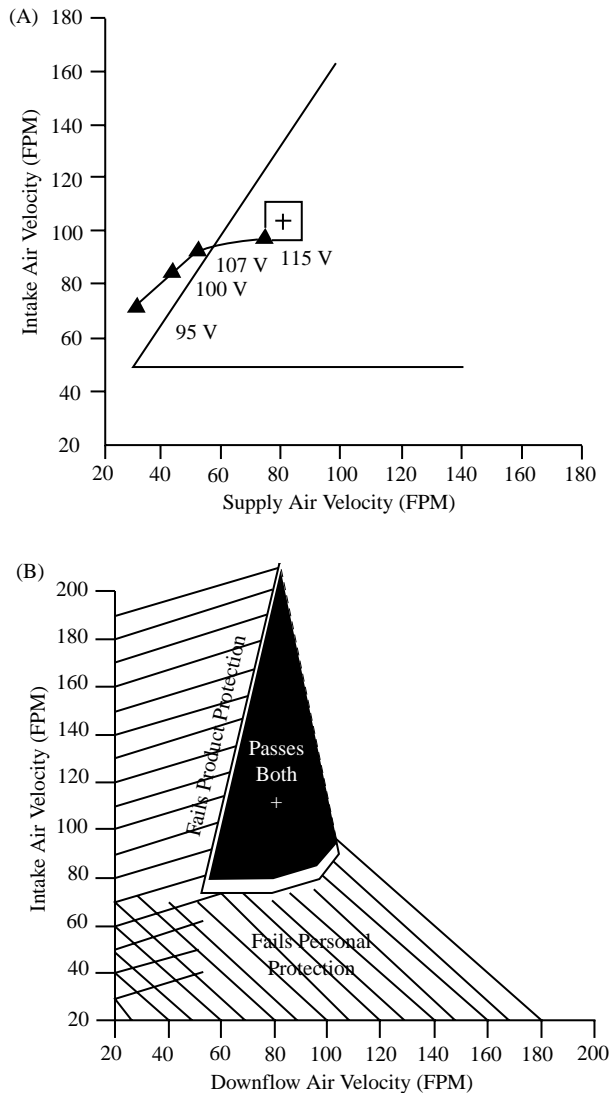

Fig. 10 (A) Effects of voltage variation on cabinet performance; National Sanitary Foundation (NSF) range, +: Normal setpoint; —: Performance envelope; ▲—▲ Airflow balance. (B) Performance envelopes for Class II BSCs determined by conducting a series of microbiological aerosol tests at a variety of airflow settings. (Courtesy of the Baker Company, Sanford, Maine.)

pressurized common space or “plenum” immediately above the entire T-bar ceiling assembly. This plenum is supplied directly by an air handler, eliminating the need for extensive ductwork. The plenum ceiling is normally used in overhead space-limited LAF applications.

The cleanroom

The cleanroom is a dedicated clean space with exacting as-built, at-rest, and operational specifications of

airborne and surface cleanliness, temperature, relative humidity, and lighting and noise levels, in which specific critical operations are carried out (11). The cleanroom may be designed to provide vertical or horizontal LAF throughout the entire room for large-scale operations requiring extended critical work zones (sterile conveyors, sterile fill operations, etc.), or may be designed as a conventionally-supplied, controlled secondary or “buffer” area, housing one or more smaller LAFD for aseptic processing steps requiring comparatively limited critical work zones.

The cleanroom is normally constructed in an existing building or structure as a core unit, surrounded by supporting access and staging anterooms, service chases, and machine rooms necessary to support the aseptic operation, supply working materials, and remove finished products and waste materials without cross-contamination or interference with the critical work stream.

TESTING AND CERTIFICATION OF LAF SYSTEMS

Thorough, periodic testing of LAF equipment is necessary to optimize performance and demonstrate compliance with established operating procedures and industry standards.

Certification

The term “certification” is widely used in connection with this type of testing. Certification may, however, only be provided by a registered testing or metrology laboratory, or other organization that derives its certification authority directly from a legitimate regulatory agency (FDA, EPA, AIHA, etc.) and which is subject to review. For a test procedure to qualify as a performance certification, the procedure must be performed and documented in accordance with the current good laboratory practices (21). All on-site testing of this nature constitutes a laboratory field certification of performance, with each test report accession-numbered in the laboratory test notebook as an actual laboratory test procedure. If the vendor of this service does not have such regulatory oversight, the buyer must qualify the vendors adequacy of experience, equipment, and efficacy of all test procedures to be performed (22), regardless of the vendor’s professional affiliations or memberships.

Fig. 11 Self-contained terminal HEPA filtration modules installed in a T-bar suspended plenum ceiling in a laminar-flow application. (Courtesy of American Air Filter, Inc., Louisville, Kentucky.)

Vendor Qualification

Although large manufacturers often have in-house personnel and facilities available to carry out LAF equipment testing, this task is frequently performed by an outside testing contractor, whose procedures and findings are relied upon without question by the buyer. Because the pharmaceutical manufacturer and pharmacy practitioner bear the ultimate responsibility to regulatory groups for ensuring compliance with all testing standards and requirements, it is essential that they select a qualified testing contractor. The buyer should interview the prospective contractor and review all aspects of the tester's training and experience, the test procedures and equipment to be used, equipment calibration and traceability, and the proposed documentation (22). The prospective contractor should be prepared to provide both company and individual resumes of qualifications, including at least three references of clients for whom the contractor has recently provided similar services (20).

Test Equipment Calibration and Traceability

The LAF equipment tester should have the equipment necessary to carry out the required challenge of the LAF system (20). This equipment should be in good working order and calibrated to a National Institute of

Standards and Testing (NIST)-traceable^r standard at least annually, or more often as indicated by the manufacturer's specifications or equipment performance (23). NIST-traceable calibration ensures the uniformity, accuracy, and serviceability of all test equipment as well as proper maintenance and care by the user. The NIST-traceability of equipment calibration is substantiated by a detailed calibration certification letter, issued by the calibrating authority for each piece of equipment.

Certification Standards

The primary standard for testing LAF equipment is a standard operating procedure (SOP), unique to the equipment or system. This SOP is normally established by the using organization to define the calibration and testing requirements of a specific LAF system, and should include the scope, intent, and frequency of testing; the equipment to be used in conducting the test; test equipment calibration; test methods and performance criteria; documentation of results; and corrective actions and acceptance. The SOP should cite the applicable references and industry standards from which it has been derived. In the absence of an organizational SOP, LAF equipment should be tested in accordance with industry standards applicable to the specific LAF

^rFormerly the National Bureau of Standards (NBS), Washington, DC.

application or area of operation (Table 3). In this case, regulatory groups will defer to these standards for proof of proper LAF system function and serviceability.

Test Reports

A comprehensive report should be issued upon completion of the test procedures, which should include all values measured for compliance, a listing of all test equipment, calculations, conversions, and all appropriate statistical justification along with comments pertaining to system function and operation. A dated test-completion or certification sticker should be affixed to the LAF unit referring any examining authority to the completed test report. All reports should include floor plans or maps of the clean space, which identify sample locations, probe heights, unusual performance characteristics, system adjustments, and repairs.

Test Procedures

Air velocity

Measurement of air velocity and laminar profile quality is the first step in LAF system testing. Using the appropriate instrument and measurement technique (4, 11, 18), the velocity of the laminar airstream for all LAFDs, and conventional buffer supply airflow volume for all controlled areas should be measured and adjusted to conform with pertinent SOPs or industry standards, consistent with the system manufacturers specifications and limitations (20).

HEPA filter performance

Following verification of the proper velocities, the HEPA filter should be aerosol-challenged in accordance with industry standards (4, 11, 18). Because this challenge is based upon the effectiveness of the filter in retaining aerosols, the upstream concentration of test aerosol should be verified before commencing this test and should not be assumed to be adequate, regardless of the circumstances.

Particle counting

Only through discrete particle counting can air cleanliness be verified, and the cleanliness class of the sampled environment established (4). Periodic in-process monitoring of workstations, buffer rooms, anterooms, production areas, and any other area about which a definitive air cleanliness statement is made or reasonably assumed, should be carried out in accordance with

SOPs or industry standards (4, 11). A discrete particle counter (DPC) with an adequate sampling rate, calibration features, and dynamic range should be used for sample acquisition, based on the specified air cleanliness level (4, 17).

Noise levels

Noise in excess of recommended levels within the LAF environment or clean space may cause operator discomfort and premature fatigue, and may indicate HEPA filter failure, or a malfunction of the LAFD or clean space air handling unit (20, 24). Cabinet pressure integrity and vibration analysis are recommended for all biological safety cabinets.

Visible and ultraviolet light levels

Visible light levels should be monitored for operator comfort and total visibility of the worksurface (20, 22). Ultraviolet germicidal light should be measured for effectiveness in all LAFDs having this feature (18).

LAMINAR FLOW CLEAN SPACE PROJECT DEVELOPMENT

As an engineering control, the demands normally placed upon an LAF system should not exceed the system's ability to provide a sterile, aerosol-free work area in which to conduct the desired aseptic operations with a high degree of confidence. Neither should a facility be overbuilt; unnecessary complication of clean space operation to achieve control levels that provide no demonstrable improvement in the process or finished product is counterproductive and an expensive waste of resources. To develop a system that is adequate for the aseptic processing task at minimum expense, a definitive, phased approach to design and implementation of the LAF system should be taken, regardless of the size or complexity of the system. The method described below ensures that any project, from a simple hood installation to a complex process cleanroom, will have the most comprehensive development and planning, thus maximizing the probability of a successful outcome.

Conceptualization

As the initial step, a thorough and complete conceptualization of the process, and the steps that will be taken to achieve the desired results should be defined in a protocol.

This document is to be used as the basis of communication with design and mechanical engineers in developing specifications for an effective and workable design, to be constructed, validated, and operated within existing cost constraints.

Protocol and Project Management

The protocol should be developed under the supervision of a project manager, selected on the basis of experience and understanding of the product, existing and intended markets, regulatory issues, the intended aseptic process, the engineering controls normally required for such a process, and the design, construction, validation, operational, and maintenance methods to be employed (25). The manager represents the owners' interests, and acts as liaison in all dealings with outside vendors and contractors. He or she should seek direct input from key personnel and representatives of all groups having direct involvement with the planned clean space (26) in meetings and discussions, as the concept evolves, with appropriate sign-off by the participants on the finished protocol. This method prevents after-the-fact, unforeseen demands upon system operation, or dissatisfaction with system performance by essential personnel. Conceptualization is based upon the following considerations:

- Space constraints vs. process requirements.
- Product or process quality statements.
- Output capacity and growth expectations.
- Industry standards and regulatory issues (Table 3).
- Cleanliness class(es) required. Identification of critical work zones and areas requiring LAF, rather than mere characterization of these areas as Class 100.
- Work streaming. Inclusion of the necessary QA/QC steps in the overall process.
- Necessary process equipment (Table 4).
- Identification of all process steps requiring an LAF environment to facilitate the desired cleanliness class. What facility and equipment performance alert and action limits are necessary, and how are these to be monitored?
- Process equipment portability and flexibility requirements. Will the process(es) be expanded or modified at some time in the future? What equipment must be permanently installed and "hard wired" within the clean space?
- Process equipment service and maintenance requirements.
- Number of personnel required.

- Personnel disciplines. What type and arrangement of anterooms are required for scrubbing, gowning, and storage of barrier materials?
- Process materials staging and waste management.
- Health and safety requirements.
- Facility housekeeping and maintenance procedures.
- Facility validation, testing, and recertification.
- Documentation, i.e., the necessary process records, logs, labels, etc., and how, when, and where these documents are produced and used.

Regulatory Issues

Operation of LAF systems in the course of pharmaceutical manufacturing and pharmacy compounding operations is ultimately scrutinized by several regulatory and quasi-regulatory groups responsible for the control and oversight of these industries. Because these regulatory groups require, almost without exception, operation of manufacturing or compounding systems in accordance with "current industry standards," the distinction between regulations and guidelines has become unclear. Guidelines, as a reflection of the most current application of any technology, often take on the weight of regulations as determinants of industry standards. As such, operation in accordance with specific industry guidelines is often required to demonstrate compliance with nonspecific or generalized regulations—i.e., current good manufacturing practices (cGMPs) or Joint Commission on Accreditation of Health Care Organizations (JCAHO) Standards. Table 3, although not intended to be all inclusive, provides a list of regulations and guidelines that are pertinent to the operation of LAF systems in several different pharmaceutical manufacturing and pharmacy-compounding applications.

Design

Based upon the protocol, the facility and process design is the next step. Whether a simple hood installation to an existing space, an upgrade retrofit of an existing space, or construction of a totally new space, the design responsibility has to be assigned and a designer chosen. The designer's obligations are considerable and should be thoroughly understood by the individual or firm retained to provide the clean space design (20).

Construction

Following completion of the design, the building contractor is chosen. The construction phase is normally

Table 4 Equipment Features and Performance^{a,b,c}

carried out with the input and assistance of the designer in conducting vendor audits for the selection of contractors with sufficient experience and facilities to complete the building tasks efficiently. Materials and workmanship audits should be carried out periodically by the project manager and the designer.

Validation and certification

Validation is described as proof that the system performs as stated. As an engineering control, the LAF system must demonstrably support the intended aseptic or controlled process. Validation of the aseptic manufacturing process and the LAF systems that support terminal sterilization in pharmaceutical manufacturing applications should be carried out in accordance with industry standards (1, 27–31). Such validation should be accomplished in three phases, consisting of installation qualification (IQ), operational qualification (OQ), and process qualification (PQ), with full and detailed documentation of all activities and outcomes (20).

Cleanroom Construction and Validation: A Low-Cost Approach

The following is a consolidation of steps leading to the construction and operation of a low-cost clean space of the type required for small- and intermediate-size drug repackagers, home health care pharmacies, and small pharmaceutical manufacturers.

Cleanroom design

The cleanroom should be conceptualized, designed, constructed, validated, operated, and maintained in a manner that supports the aseptic process. A construction plan, including reasonable time frames for the acquisition of labor and materials should be developed, followed, and updated. All work and materials should comply with local building codes and safety ordinances.

HEPA Filtration

Computation of the air change rate (AC) necessary for the desired cleanliness class is the initial step in determining the ceiling module filter density required for the clean space, and should be calculated accurately, with sufficient redundancy to assure the required airflow and resulting cleanliness levels (20, 32,33).

Air Handling

Air handling requirements should be calculated, and air handler type and capacity should be matched to the AC rate, heating, cooling, and dehumidification requirements of the facility (34), as calculated from the reflected ceiling plan. At almost any intended level of processing, low cost, “turn-key” air handling systems are available with a minimum of lead time. They are easily installed, operated, and maintained. The installation of a modular air handler of this type provides conditioned air, allowing operation of the core and anteroom areas as an independent facility, without dependence upon a central building air handling apparatus for process control. This type of low-cost, modular air handler, in a single-or multiple-unit installation, facilitates complete treatment and conditioning of the supply air to be provided in quantities adequate to maintain the most stringent air cleanliness classes for workstations and general room air, as well as temperature and relative humidity at recommended core and anteroom internal operating pressures. In addition, several manufacturers of this type of unit have experienced, on-staff mechanical engineers qualified to assist the buyer in determining the exact air treatment and handling requirements for a specific application at no additional charge. Qualification of the knowledge and experience of all individuals involved in the conceptualization and design phases is necessary, and references should be obtained and checked by the buyer.

Differential Pressurization

The cleanroom facility should be carefully designed to control the ingress of contaminants, and be positively pressurized to the surrounding area in accordance with industry standards. The core and anterooms are positively pressurized by varying the amount of incoming “make-up” air (20). In the case of “soft wall” clean space facilities, such pressurization (potential outflow) is not possible, and a sufficient amount of constant, active outflow (kinetic outflow) should occur to prevent ingress of contaminants.

Lighting and Electrical

Electrical service should be provided in the normal fashion in accordance with local building and electrical codes. Clean space service requires no special treatment, and should provide a 25–50 A surplus over worst-case processing demands, to allow for additional electrical

equipment and source power fluctuations. Fixture types, sealable outlets, and hard-wiring of processing equipment should be selected and carried out in accordance with industry standards and electrical codes (20).

Walls and Windows

Walls should be typical 5/8-in. drywall over metal studs at 16-in. centers, and may be insulated or not as deemed appropriate. The inner clean space wall should be finished with enameled panels (available at most building supply outlets) that are butted and sealed with RTV silicone, to provide gas-tight seams between the wall panel, ceiling T-bar, and floor base junctions. (Clear RTV silicone is recommended, neatly and sparingly “mopped in,” with all residues cleared away while still wet; this method creates an invisible, water-tight seal facilitating long term serviceability and ease of cleaning.) The outer walls should be painted with cleanable epoxy enamel or suitably covered, and a long, narrow observation window (recommended aspect 1:8–10, without ledge), or a series of double-pane, ledgeless windows should be installed and finished to provide complete observation of the operational process by prospective clients, supervisory personnel, and others.

Floor

The anteroom and core flooring should be an attractive, highly durable, one-piece vinyl or other suitable floor material, providing a minimum of seams. This flooring should ideally radius in a cove at the wall base and continue upward to a height of 8 inches. to 1 ft above the floor. At that point it should be capped with a suitable beading, sealed by RTV silicone, neatly “mopped in,” and allowed to dry. No drain or other floor opening should be permitted in the core; a small, single drain may be permitted in the anteroom in the event carts or other materials are to be cleaned and staged in that area. The floor should be routinely cleaned by a wet-vac recovery of a spread floor cleaning solution (with hose and head located within the clean space, with pass-through connection to a vacuum source located and vented outside the clean space).

Ceiling

The anteroom and core ceilings should be of typical 1.5 in. T-Bar construction, with seismic restraints adequate

to support the HEPA terminals, lighting fixtures, and ceiling panels. The panels may be obtained from clean space suppliers in the form of finished “cleanroom” ceiling panels, or by reduction of additional enameled wall panels to 2 × 4 ft (nominal) panels, affixed by permanent adhesive to standard, plain face (nontextured), fire-rated, 0.5 inches. commercial ceiling panels, which are easily installed and RTV silicone-sealed in place. This allows installation of a permanent, gas-tight ceiling, washable like the walls and floor, and attractive in that it provides visual continuity of the wall material.

Doors and Pass-Throughs

Doors and pass-throughs should facilitate easy, integral entry and exit of personnel and working materials (20).

Construction

Construction of the facility should be based upon the completed design and incorporate normal construction methods, tools, and techniques. Special preparation of components is necessary, including a general cleaning and protection of components and equipment from potential sources of contamination during the construction phase. The working materials should be protected from atmospheric dust, sawdust, grease, aerosols of oil, and other residues, which may be encountered during construction, using “clean construction” methods (20).

Validation

Following completion of all testing and certification of the facility, documentation should be developed and retained, which may be used as proof of performance in accordance with the protocol in the as-built configuration (4, 11). Periodic retesting and monitoring at specified intervals in the at-rest and operational modes (4, 11) should be carried out to maintain operation of the facility in accordance with SOPs or industry standards.

Operation

Operation of the facility in accordance with validation conditions, through the use of appropriate SOPs and industry standard quality management parameters (28) should be commenced following validation, incorporating the necessary alert and action limits, monitoring

procedures and maintenance steps to be carried out and included in the production cycle documentation. All microbiologic monitoring of the clean space ante-rooms, core, worksurfaces and personnel barriers should be carried out in a systematic manner by experienced personnel (35).

Personnel Selection and Validation

Because the effectiveness of operative personnel is potentially the greatest variable in any controlled process, a selection, training, examination, and grading system should assure the suitability of candidates, the adequacy of training, and the ultimate uniformity and consistency of clean space operating procedures (12, 14, 15, 36).

Maintenance

Clean space maintenance SOPs and documentation should be developed and followed in strict accordance with industry standards (13) to ensure the consistency of operation in accordance with validation conditions.

ISOMERISM

Thomas N. Riley

Jack DeRuiter

William R. Ravis

C. Randall Clark

Auburn University, Auburn, Alabama, U.S.A.

BASIC PRINCIPLES

Isomers are defined as molecules of identical atomic compositions (molecular formulas), but with different bonding arrangements of atoms or orientation of their atoms in space. Based on this definition, several types of isomerism are possible including constitutional, configurational, and conformational isomerism. Constitutional isomers (also called structural or positional isomers) are molecules with the same atomic composition but different bonding arrangements between atoms, as illustrated by the examples of catechol, resorcinol, and hydroquinone (Fig. 1). All of these compounds have the same atomic composition ($C_6H_6O_2$), but different bonding arrangements of atoms and are thus distinct chemical entities with different chemical and physical properties.

Configurational isomers are defined as molecules of identical atomic composition and bonding arrangements of atoms, but different orientations of atoms in space, and these different orientations cannot interconvert freely by bond rotation. Since these types of isomers differ only in relative spatial orientations of atoms, they are commonly referred to as stereoisomers. Configurational stereoisomers are subcategorized as optical isomers (enantiomers) or geometric isomers (Fig. 2), depending upon the hybridization state and geometry of the atoms that impart the properties of stereoisomerism and the overall structure of the molecule. Stereoisomers of this type are distinct chemical entities that may have different chemical and physical properties.

Conformational isomers (conformers) are stereoisomeric forms characterized by different relative spatial arrangements of atoms that result from rotation about sigma bonds. Thus, unlike configurational isomers, conformers are interconverting stereochemical forms of a single compound. The nature of conformational and configurational stereoisomerism, as well as the role of stereoisomerism in drug activity is the subject of this article.

Optical Activity and Molecular Structure

Modern stereochemistry originated with the research of Malus in 1808 who discovered that plane-polarized light is generated when a beam of light is passed through calcium carbonate. In 1813, the mineralogist Biot reported that asymmetrically cut quartz crystals rotate the plane of a beam of polarized light. It also was noted that certain organic liquids, as well as solutions of certain organic compounds, can rotate the plane of polarized light. Biot attributed this effect on plane-polarized light to a property of the individual organic molecules through which the light is passed, a property now referred to as optical activity. The concept of optical activity was extended by Herschel in 1812, who observed that hemihedral quartz crystals, having odd faces inclined in one direction, rotated the plane of polarized light in one direction, whereas crystals whose odd faces were inclined in the opposite direction rotated plane-polarized light to the same extent but in the opposite direction.

Pasteur refined the observations of the mineralogists by proposing a link between optical activity and molecular structure. His landmark work of 1847 was based on earlier observations by Biot that chemically identical salts of tartaric acid rotated plane-polarized light differently. Pasteur discovered that two distinct crystalline forms of tartaric acid salt could be obtained from solutions of the optically inactive salt of "paratartaric acid" (also known as racemic acid), and that one crystal form has hemihedral faces that inclined to the right, whereas the other has faces that inclined to the left. He separated the distinct crystalline salts forms and observed that they, unlike paratartaric acid, are optically active; solutions of the left-handed crystals rotate the plane of polarized light to the right, and solutions of the right-handed crystals rotate the light to the same degree, but in the opposite direction. Pasteur further demonstrated that the left- and right-handed crystals were mirror images of each other and concluded that this property must reflect the handedness of the molecules that constitute the crystals.

Fig. 1 Constitutional isomers.

Fig. 2 Stereoisomers.

The molecular basis for the left- and right-handedness of distinct crystals of the same chemical substance and the associated differences in optical rotation was developed from the hypothesis of Paterno (1869) and Kekulé that the geometry about a carbon atom bound to four ligands is tetrahedral. Based on the concept of tetrahedral geometry, Van't Hoff and LeBel concluded that when four different groups or atoms are bound to a carbon atom, two distinct tetrahedral molecular forms are possible, and these bear a nonsuperimposable mirror-image relationship to one another (Fig. 3). This hypothesis provided the link between three-dimensional molecular structure and optical activity, and as such represents the foundation of stereoisomerism and stereochemistry.

Chirality and Optical Isomers (Enantiomers)

The property of nonsuperimposability became known as chirality, and molecules containing asymmetrically substituted carbons are referred to as chiral molecules. The term chiral was derived from the Greek word meaning "hand" and was applied as a description of the left- and right-handedness of crystal structure resulting from molecular asymmetry. The individual mirror image forms

Fig. 3 Tetrahedral geometry and optical isomerism.

Fig. 4 Amphetamine enantiomers.

of a chiral molecule are called optical isomers because they rotate the plane of polarized light (are optically active) and differ in structure only in the orientation of atoms or groups about the asymmetric carbon (are isomers). Today, optical isomers are more commonly referred to as enantiomers or an enantiomeric pair.

Generally, optical isomers or enantiomers have identical physical and chemical properties, for example, the enantiomeric forms of amphetamine (Fig. 4) have identical melting points, pK_a , solubilities, etc. There are, however, two important differences in properties between the members of an enantiomeric pair. First, each member rotates the plane of polarized light to the same degree, but in opposite directions. The enantiomer rotating the plane to right (clockwise) is designated as the dextrorotatory (d) or (+)-enantiomer. The other enantiomer rotates the plane to the left (counterclockwise) and is designated as the levorotatory (l) or (–)-enantiomer. This is illustrated in Fig. 4 for the enantiomers of amphetamine, where the enantiomer with the specific optical rotation of (+)-21.8° is designated as dextrorotatory, whereas the mirror enantiomer with a specific rotation of (–)-21.8° is called levorotatory. A second difference between enantiomers is their interactions with other chiral substances. For example, enantiomers may have different solubilities in chiral solvents, they may react at different rates in the presence of an optically active reagent or enzyme, and many have different affinities for chiral surfaces and receptors.

Most optically active drugs are chiral as a result of the presence of an asymmetrically substituted tetrahedral carbon atom. However, chirality can result from the

Fig. 5 Optical isomers of cyclophosphamide.

Fig. 6 Pyramidal inversion of chiral nitrogen.

presence of other asymmetrically substituted atoms within molecules as illustrated below including phosphorous (Fig. 5), nitrogen (Fig. 6), and sulfur (Fig. 7).

Definitions and Nomenclature

As discussed in the preceding section, each member of an enantiomeric pair rotates the plane of polarized light to the same degree, but in opposite directions (dextrorotatory and levorotatory). However, the amount of optical rotation is not constant for an individual enantiomer but rather is dependent on the solvent, concentration, temperature, the wavelength of light used, and the path length of the sample cell employed to determine the rotation. Thus, meaningful optical rotation comparisons for chiral compounds are only possible when optical activities are determined under specified conditions. Such conditions are defined as specific rotations $[\alpha]$ and are expressed for solutions and neat liquids in Eq. 1 and 2, respectively.

$$[\alpha]_{\lambda}^t = \frac{100\alpha}{l \cdot c} \quad (1)$$

$$[\alpha]_{\lambda}^t = \frac{\alpha}{l \cdot d} \quad (2)$$

where α is the measured rotation; t , the temperature; λ the wavelength; c , the concentration; d , the density; and l , the length.

Specific rotation data may assist in the identification of a specific enantiomer, or may be used to determine the optical purity (enantiomeric purity) of a mixture of enantiomers. Optical purity is defined as the percent excess of one enantiomer over another in a mixture and is expressed in Eq. 3:

$$\text{Optical purity} = \frac{[d] - [l]}{[d] + [l]} \cdot \frac{\alpha_{\text{obs}}}{\alpha_o} \quad (3)$$

Based on Eq. 3, a mixture consisting of equal amounts of each enantiomer would have no net optical rotation; the optical rotation of one enantiomer is cancelled by the rotation of the other enantiomer. Such a mixture is referred to as a racemic mixture or racemate.

Other terms commonly applied in discussions of optically active compounds include resolution and

Fig. 7 The chiral sulfoxide sulindac.

racemization. Resolution describes the processes whereby a racemic mixture is separated (resolved) into its component enantiomers. Racemization refers to the conversion of either enantiomer into equal parts (racemic mixture) of both enantiomers.

Over the years, several nomenclature systems have been developed to characterize the relationship between enantiomers. The system based on optical activity and the classification of enantiomers as dextrorotatory [d or $(+)$] or levorotatory [l or $(-)$] already has been described. However, this system of nomenclature is of limited applicability because the sign of rotation, $(+)$ or $(-)$, does not predict the absolute configuration or the relative spatial arrangement of atoms in the enantiomers. In an attempt to designate the precise configurations about carbon centers of asymmetry, the Cahn–Ingold–Prelog R/S system have been developed and adopted as the most commonly used nomenclature system for isomers.

In applying the Cahn, Ingold, and Prelog R/S system the compound is oriented in a Fischer projection and the four groups or atoms bound to an asymmetric carbon are ranked by the following set of sequence rules (Fig. 8):

1. Substituents are ranked (1–4) by the atomic number of the atom directly joined to the chiral carbon.
2. When two or more of the atoms connected to the chiral carbon are the same, the atomic number of the next adjacent atom determines the priority. If two or more atoms connected to the second atom are the same, the third atom determines the priority, etc.
3. All atoms except hydrogen are formally given a valence of 4. When the actual valence is less than 4 (N, O), phantom atoms are assigned an atomic number of zero and therefore rank the lowest.
4. A tritium atom has a higher priority than deuterium, which has a higher priority than hydrogen. Similarly, any higher isotope has a higher priority than any lower one.

S-Glyceraldehyde *R*-Glyceraldehyde

Fig. 8 Cahn–Ingold–Prelog sequence rule.

5. Atoms with double and triple bonds are counted as if they were connected by two or three single bonds. Hence a CC is regarded as a carbon bound to two carbons; and a CO is regarded as a carbon bound to two oxygens.

Once the four groups bound to the chiral carbon are ranked, the compound is oriented in such a way that the lowest priority group (4) is projected away from the observer. Then, if the other groups (1–3) are oriented by priority in a clockwise fashion, the molecule is designated as *R* (rectus), and if counterclockwise, as *S* (sinister). These sequence rules are applied in the assignment of the absolute configurations for the enantiomers of glyceraldehyde in Fig. 8. According to the first rule, the highest priority substituent (1) is the hydroxy group (OH) and the lowest priority group (4) is the hydrogen atom; since the atomic number of carbon is higher than that of hydrogen but lower than that of oxygen, the two carbon substituents (CHO and CH₂OH) are assigned intermediate priorities. To determine the priority relative to the two carbon substituents, both the 2nd and 5th rules must be applied. The aldehyde carbon is part of a carbonyl (C=O) moiety which, by rule 5, is equivalent to a carbon bound to two oxygen atoms. The alcohol carbon (CH₂OH) is bound to one oxygen and two hydrogens. The “two oxygens” of the aldehyde take priority over the single oxygen of the alcohol moiety; the aldehyde is assigned priority 2, and the alcohol priority 3. With all substituents ranked and the enantiomers oriented in such a way that the lowest priority group (4) is projected away from the observer, the configurations can be assigned. The enantiomer in which the substituents are oriented by priority in a clockwise fashion, is designated as *R*, and the enantiomer in which the substituents are oriented by priority in a counterclockwise direction is designated as *S*.

Compounds with Multiple Centers of Asymmetry

Many stereoisomeric drugs contain more than one asymmetrically substituted atom. For example, ephedrine has two chiral centers (Fig. 9). In this case, a greater

Ephedrine

Fig. 9 Ephedrine having multiple chiral centers.

number of configurational isomers is possible; the maximum number possible is 2^n , where n is the number of chiral atoms. Hence, the maximum number of possible configurational isomers for ephedrine is four, which are designated *RR*, *SS*, *RS*, and *SR* (Fig. 10). The *RS* and *SR* isomers are nonsuperimposable mirror images and hence are enantiomers. The same relationship exists for the *RR* and *SS* isomers. The relationship between each member of an enantiomeric pair and each member of the other enantiomeric pair is diastereomeric; they are nonsuperimposable nonmirror images. Thus, the *RS* isomer is a diastereomer of the *RR* and *SS* isomers, and the *SS* isomer is a diastereomer of the *RS* and *SR* isomers. In this case, the *SR* and *RS* enantiomers are referred to as ephedrines, whereas the *RR* and *SS* enantiomers are called pseudo-

Fig. 10 Ephedrine and pseudoephedrine stereoisomers.

ephedrine. Diastereomers, unlike enantiomers, differ in their physicochemical properties including solubilities, acid-base strengths, melting points, etc.

In addition to the *R* and *S* designations, compounds with two chiral centers may also be identified by stereochemical nomenclature that describes the entire system. For example, the *erythro* and *threo* nomenclature derived from carbohydrate chemistry may be employed to describe the relative positions of similar groups on each chiral carbon. Thus, the ephedrine isomers are designated as *erythro* forms since the similar groups (OH and NHCH₃) are on the same side of the vertical axis of the Fischer projection, and the pseudoephedrine isomers are designated as *threo* forms since like groups are on opposite sites of the vertical axis of the projection (Fig. 10).

It is important to note that the 2ⁿ rule predicts only the maximum number of stereoisomers possible in compounds with more than one center of chirality. For example, some compounds with two asymmetrically substituted carbon atoms may have only three stereoisomeric forms. This

occurs when three of the substituents on one asymmetric carbon are the same as those on the other asymmetric carbon, as shown for the antitubercular ethambutol (Fig. 11). In this case, one stereoisomer has a plane of symmetry even though two asymmetric atoms are present. Such an isomer is referred to as a *meso* compound and is optically inactive. Therefore, when a plane of symmetry is present in a compound with two centers of asymmetry, only three stereoisomeric forms are possible.

Geometric Isomerism

Geometric isomerism was first defined by Wislicenus in 1887 as isomerism occurring in compounds where rotation is restricted by double bonds or ring systems. Geometric isomers do not rotate the plane of polarized light (unless they also contain a chiral center), and hence are not optically active.

Geometric isomerism resulting from restricted rotation about double bonds

The sp² hybridized carbon atoms of alkenes (olefins) and the atoms or groups attached to these carbons all lie in the same plane, and rotation around the double bond is restricted. As a result, stereoisomerism is possible when each carbon atom of the double bond is asymmetrically substituted. Because geometric isomers are nonsuperimposable, nonmirror images they are classified as diastereomers and therefore possess different physical and chemical properties. A number of drugs contain dissymmetrically substituted carbon-carbon double bonds and therefore can exist as two distinct geometric isomers (Fig. 12).

Several systems of nomenclature have been developed to designate the configuration of geometric isomers. Historically, the *cis-trans* system of nomenclature has been applied most frequently. It was developed to assign the configuration of geometric isomers when each isomer contains a like group or atom on each carbon atom of the double bond. However, in more complex structures this

Fig. 11 Ethambutol stereoisomers.

Fig. 12 Pharmacologically active dissymmetrically substituted alkenes.

system cannot be used unambiguously to assign configurations for all geometric isomers. For example, the sp^2 atoms of the antipsychotic agent thiothixene do not contain a like atom or group (Fig. 13). Thus, the *E/Z* notation system was developed to unambiguously assign configurations in all cases of geometric isomerism.

1. Priorities are assigned on the basis of atomic number for the two atoms or groups attached to each carbon of the carbon–carbon double bond. The same priorities apply as in the Cahn–Ingold–Prelog sequence rules.
2. Configuration is assigned based on the relative positions of the highest priority atoms or groups on each carbon of the carbon–carbon double bond. If these groups are on the same side, the *Z* (zusammen) designation is used. If they are on the opposite side, the *E* (entgegen) designation is assigned.

Geometric isomerism is also possible in double-bonded carbon-heteroatom systems such as imines and oximes (CN), and in azo (NN) systems. For example, several cephalosporin derivatives contain an alkoxyimino side chain that may exist in *E* or *Z* isomeric forms; the azo compound prontosil may display similar isomerism (Fig. 14). A *syn-anti* system can also be applied to CN geometric isomers. In these cases, the priority assignments are made as described previously, and the isomer with highest priorities on the same face of the double bond are called *syn*, whereas those with these groups on opposite sides are named *anti*.

In a number of amides, thioamides, and related systems, rotation about the single bond is hindered, and distinct geometric isomers can be observed and even isolated. This type of geometric isomerism is referred to as atropisomerism and results from resonance contributions by the nitrogen atom that imparts significant double bond character to the system, thus slowing rotation. Such is the case for the thioamide aldose reductase inhibitor

Fig. 13 Geometric isomer nomenclature—thiothixene.

Fig. 14 Geometric isomerism about C-heteroatom double bonds.

Fig. 15 Atropisomerism, tolrestat.

Fig. 16 Geometric isomerism in cyclic drug structures.

tolrestat shown in Fig. 15. Isomers of this type are also called rotamers and are considered to be conformational isomers since they result from rotation about a single bond.

Geometric isomerism in cyclic compounds

The presence of a ring system, either cycloaliphatic or heteroaliphatic, like that of a double bond, prevents rotation, therefore giving rise to geometric isomers when two carbon atoms of the ring are each substituted by different groups. Structures of pharmacologically-important structures that display geometric isomerism are shown in Fig. 16.

When rings are fused through adjacent atoms, the fusion may be *cis* or *trans*, as illustrated by the steroid structure (Fig. 16). In the naturally occurring steroids the ring junctions are all *trans*, except in the case of the cardiac glycosides where both A/B and C/D junctions are *cis*. Rings fused through nonadjacent atoms, or bridged systems, may also display stereoisomerism.

Conformational Isomerism

In the preceding sections the nature and properties of configurational (optical and geometric isomers) were discussed. It is important to remember that configurational isomers are distinct, separable compounds.

Fig. 17 Newman projection formulas for staggered and eclipsed rotamers.

Conformational isomers are different three-dimensional arrangements in space of the atoms of a single compound or configurational isomer. Such isomers are termed conformers and are interconvertible by free rotation about single bonds.

In alkanes or alkyl systems, an infinite number of conformations is possible as a result of rotation about CC single bonds, and each conformation has a certain potential energy. Two conformational extremes, one of low (minimal steric interaction between bond substituents) and one of high (maximal steric interaction) potential energy, have been described for these systems. These are depicted as Newman projections in Fig. 17. A more recent nomenclature system for conformational isomers arising from energy barriers associated with rotation about a C–C single bond is shown in Fig. 18. In this case, the most stable conformer is the antiperiplanar isomer, where the distance between the two bulky groups (X and Y) is maximized, thus minimizing steric interactions. The least stable conformer is the fully eclipsed or synperiplanar conformer where the two groups are closest together. The other conformers, the anticlinal and gauche or synclinal are of intermediate stability.

Conformational isomerism is believed to be of great significance for drug-receptor and drug-enzyme

Fig. 18 Conformational isomers.

Fig. 19 Pharmacophoric conformations of acetylcholine and norepinephrine.

interactions. For example, experimental data suggest that catecholamines such as norepinephrine and dopamine interact with their receptors in the antiperiplanar conformation. Furthermore, the preferred (pharmacophoric) conformation of acetylcholine at its muscarinic receptor sites is the synclinal conformer (Fig. 19).

Conformational isomerism in cycloalkyl and cycloheteroalkyl structures is characterized by several different conformational extremes. For example, cyclohexane systems can exist in three distinct conformations: boat, twist boat, and chair. Of these, the chair form is the most stable conformation because steric interactions are minimized (Fig. 20). The substituents present on a ring conformer are designated as axial or equatorial, depending on the direction of projection from the average plane of the carbon skeleton. Substituents that project directly up or down from the ring are axial, and those in the plane of the ring are equatorial. Because of the conformational flexibility of cycloalkanes such as cyclohexane, the ring conformation can invert. During inversion, all axial substituents become equatorial and all equatorial substituents become axial.

Ring conformations are believed to be important in drug activity. For example, experimental evidence suggests that the analgesic fentanyl binds to opiate receptors preferentially in the conformation shown in Fig. 21, where the

Fig. 20 Conformational isomerism of cycloalkanes.

Fig. 21 Conformational isomerism, 3-methylfentanyl.

bulky substituents are positioned equatorially to minimize conformational instability.

PHARMACOLOGICAL ASPECTS OF ISOMERISM

Background and Definitions (1, 2)

Structural and steric complementarities of drug molecules with their target sites of action are essential criteria for the production of a pharmacological effect. The requirement of stereocomplementarity for organic medicinal agents reflects the inherent dissymmetry of the biological system comprised of stereoisomeric proteins, amino acids, lipids, carbohydrates, nucleic acids, etc. Molecular dissymmetry of biological systems was initially demonstrated in the 1880s by Pasteur. Then in 1908 Cushney explained differences in pharmacological actions of epinephrine enantiomers on the basis of dissymmetric drug receptors. Easson and Stedman in 1933 proposed a model for the molecular basis of sympathomimetic amines stereoselectivity at adrenergic receptors based on optimization of the number of interactions for each stereoisomer. Hence, the more efficacious (*R*)-(-)epinephrine isomer can achieve a three-point receptor interaction while the less active (*S*)-(+)-enantiomer and its achiral desoxy analogue, dopamine, can only achieve a 2-point interaction (Fig. 22). While Easson–Stedman's description of stereoisomeric drug action is a rather simplistic approximation of the steric aspects of drug action, it served to stimulate concerted chemical and pharmacological study of the phenomenon of stereoselectivity of drug action. Pfeiffer's rule, an attempt to quantifying drug stereoselectivity, states that, in the case of enantiomeric drugs, the greater the activity of the racemate the higher the ratio of the enantiomer's activity. A quantitative treatment of stereoisomeric drug action is the technique of eudismic analysis, which is most commonly applied to studies of enantiomeric drug action. In an eudismic analysis, the more active enantiomer (e.g., higher receptor

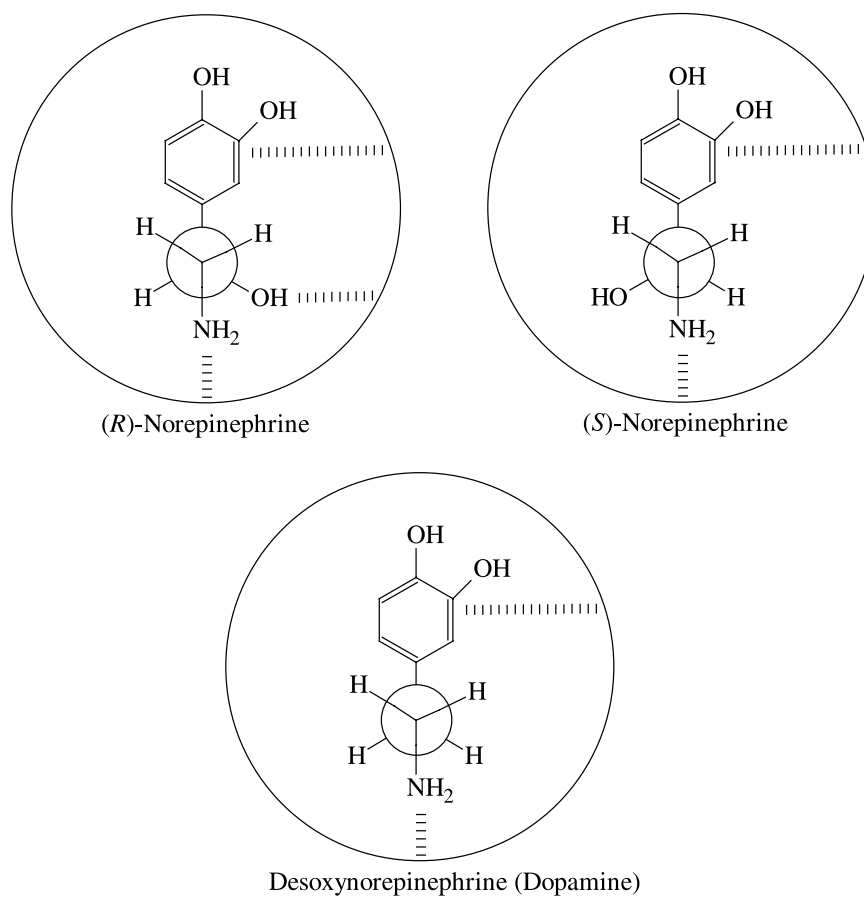

Fig. 22 The Easson-Stedman hypothesis of stereoisomeric drug action.

affinity—aff) is termed the eutomer and its less active mirror image form (e.g., relatively lower receptor affinity) is referred to as the distomer. Stereoselective pharmacological profiles of an enantiomer can be quantitated as a ratio of specific pharmacological actions termed the eudismic ratios (Eq. 4). The logarithm of the eudismic ratio is termed the eudismic index (Eq. 5).

$$\text{Eudismic ratio (ER)} = \text{Aff}_{\text{eu}} + \text{Aff}_{\text{dis}} \quad (4)$$

$$\text{Eudismic index (EI)} = \log \text{Aff}_{\text{eu}} + \text{Aff}_{\text{dis}} \quad (5)$$

Steric Aspects of Drug Action (3–7)

It is estimated that approximately one-half of all drugs worldwide exist as stereoisomers. However, only one-half of stereoisomeric drugs are marketed as the individual stereoisomer and most of the latter are of natural or semi-synthetic origin. There is increasing awareness of the clinical importance of drug stereoselectivity because differences in the behavior of isomers in the chiral living

system can result in significant differences in clinical outcomes. Table 1 presents a number of examples of these difference.

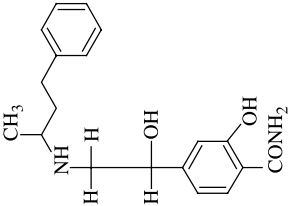

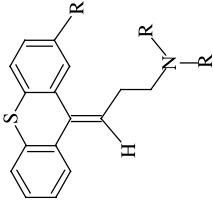

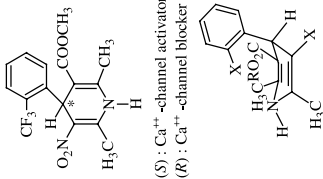

The previous examples have described the varying influences of chirality on pharmacological activity. Table 1 also illustrates the influence of other types of stereoisomerism on the pharmacological profiles of medicinal agents including that of geometric isomerism on the antipsychotic activity of thioxanthene derivatives. The eutomeric relationship of the Z-thioxanthene has been ascribed to its greater conformational complementarity with the pharmacophoric extended conformation of that natural receptor ligand dopamine. Both conformational and configurational isomerism are important in the pharmacological actions of the calcium-channel-blocking 1,4-dihydropyridines. Unsymmetrical ester substitutions at C3 and C5 result in chirality at C4 with the enantiomers of selected derivatives possessing opposite effects on calcium-channel function. Further, the availability of a “boat-like” conformation of the dihydropyridines has been

Table 1 Steric aspects of drug action

Stereoisomeric drug	Structure	Comments
<i>R</i> - and <i>S</i> - α -Methyldopa		Only the <i>S</i> isomer possess pharmacologic activity (stereo specificity of action) because only the <i>S</i> isomer can be stereoselectively bioactivated to (1 <i>R</i> ,2 <i>S</i>)- α -methylnor-epinephrine, a presynaptic α 1-sympatho-mimetic antihypertensive.
<i>R</i> - and <i>S</i> -Flecainide		An example of a lack of stereoselectivity of pharmacological action. The enantiomers of flecainide demonstrates an eudismic ratio of \sim 1.0 on excitable tissue of the canine myocardium.
<i>R</i> - and <i>S</i> -Warfarin		The anticoagulant activity of warfarin is a classic example of stereoselective drug action. <i>S</i> -warfarin in vivo is from two- to five-fold more anticoagulant than its <i>R</i> -enantiomer. This potency difference is coincidentally offset by the two-or five-fold greater plasma clearance of the distomer.
<i>R</i> - and <i>S</i> -Albuterol		The <i>S</i> -isomer of albuterol has been shown to oppose the bronchodilatory effects of the eutomer, <i>R</i> -albuterol and may therefore contribute to paradoxical bronchospasm and the occurrence of severe reagenic-like reactions seen with racemic albuterol.
<i>R</i> - and <i>S</i> -Bupivacaine		Bupivacaine exhibits stereoselectivity of local anesthetic activity, CNS and cardiac toxicity and pharmacokinetics. <i>R</i> -Bupivacaine is more potent, more toxic and more rapidly cleared than its <i>S</i> -isomer.

(Continued)

Table 1 Steric aspects of drug action (Continued)

Stereoisomeric drug	Structure	Comments
Labetalol stereoisomers	 <p>Labetalol stereoisomers</p>	These stereoisomers provide an example of different but complementary pharmacological of stereoisomers contributing to overall therapeutic utility. <i>R,R</i> -labetalol is a selective β -sympatholytic while the <i>S,R</i> -isomer is an α_1 -adrenolytic eutomer.
Antipsychotic thioxanthenes		Z-orientation of the propylamine side chain enhances dopamine receptor site recognition of these agents.
Dihydropyridine derivatives	 <p>(<i>S</i>) : Ca^{++} -channel activator (<i>R</i>) : Ca^{++} -channel blocker</p>	Unsymmetrical ester substitutions at C3 and C5 result in chirality at C4 of the dihydropyridines. Separation of pharmacological actions is seen in appropriately structures optical isomers of chiral dihydropyridines. Further, the availability of a “boat-like” conformation of the dihydropyridines has been proposed to facilitate the calcium channel blocking activity of this class of agents.

proposed to facilitate the calcium channel blocking activity of this class of agents.

Hence it is obvious that stereoisomeric influences as well as structural effects, play a major role in the production of the pharmacological profiles of medicinal agents. Variations noted in vitro that are related to the three-dimensional shape of a drug molecule originate primarily in stereoselective processes involved in the target site. In vivo variations related to stereochemical influences reflect selective interactions of the drug both at its site of action and in the various phases of biodisposition.

STERIC ASPECTS OF PHARMACOKINETICS

The macromolecules of the body can distinguish between drug isomers leading to stereoselective differences in tissue and protein binding, biotransformation, and renal excretion. Slight spatial differences in stereoisomers can have marked effects on the degree of association and interaction with proteins and enzyme systems. Stereoisomeric drugs often display stereoselectivity in pharmacokinetic processes and pathways that require interaction and association with macromolecules and enzymes systems. Furthermore, diastereomers display a higher degree of stereoselective than enantiomers due to their differences in solubility and partitioning. Since enantiomers have identical solubility and partitioning characteristics, their stereo selective pharmacokinetics are expected to reside in more structurally specific processes such as membrane transport, biotransformation, and binding to proteins and tissues.

Drug Absorption

The passive gastrointestinal absorption of enantiomeric drugs would be expected to be similar since the physical properties of partitioning and solubility of enantiomers are the same. Transdermal absorption of drugs such as ketoprofen also appears to be nonstereo specific (8).

Stereoisomers with structural similarities to endogenous entities and nutrients display differences in permeability rates across the gastrointestinal membrane and hence in bioavailability. L-DOPA, which is absorbed by an amino acid transport system, passes the gastrointestinal wall at a rate four to five times that of the D-enantiomer (9). L-methotrexate is absorbed by active processes in the gastrointestinal tract, and the D-isomer is reportedly absorbed by passive absorption. Another example of enantiomeric effects on gastrointestinal absorption is the

reported stereoselective absorption and intestinal biotransformation of cephalixin in rats (10).

In addition to stereospecific membrane permeability, there is a potential for stereoselective drug and dosage form effects. The crystalline forms of racemates may not be the same as the crystal structures of the individual stereoisomers and may be a source of differences in rates of dissolution between racemic and single enantiomer dosage forms. With respect to formulation, stereoselective interactions between solid dosage form excipients that are chiral, such as cellulose derivatives, may have the potential of altering the dissolution rates of stereoisomers. Further investigations of excipients and dosage form influences on the dissolution of chiral drugs are needed.

Drug Distribution

The extent and degree of interactions between chiral macromolecules of the body and stereoisomers is a source of observable differences in isomeric drug distribution. Stereoselectivity in drug distribution may occur when tissue or protein binding or uptake is associated with structurally specific receptor, protein, or enzyme binding. Since only unbound or free drug is susceptible to elimination and distribution to receptors and other tissues and fluids, differences in the protein and tissue binding of stereoisomers are reflected in their overall pharmacokinetic profiles.

Stereoselective interactions with both isolated human albumin and α_1 -acid glycoprotein have been observed with a variety of protein-binding techniques. The interaction of an enantiomer with a plasma protein yields a diastereomeric association. The *S* isomer of warfarin is bound to a greater extent to albumin than the *R* isomer (11). α_1 -Acid glycoprotein binds *S*-propranolol (87.3%) to a slightly higher degree than *R*-propranolol (83.8%), whereas human albumin binds *R*-propranolol more strongly than the *S* form (12).

The extent of binding differences between isomers is most readily noted from ratios of fractions free in the plasma; this ratio can be as high as three (Table 2). Recognizing that plasma protein binding impacts on drug distribution and elimination, differences in plasma protein binding between stereoisomers may lead to misinterpretation of pharmacokinetic comparisons between isomers, unless protein binding of the isomers is considered.

For enantiomeric drugs with low organ clearance, differences in renal or hepatic clearance between stereoisomers may reflect their free fraction in the plasma and not real stereoselectivity of the ability of the organ to remove the free enantiomers (intrinsic clearance) from the plasma. Clearance differences between stereoisomers of

^a(Ref. 26.)^b(Ref. 14.)^c(Ref. 12.)^d(Ref. 59.)

verapamil and disopyramide may be a function of plasma protein binding differences. In addition, volumes of distribution as well as concentration ratios of stereoisomers in body fluids to total plasma and blood are influenced by plasma protein binding. For example, the larger volume of distribution and greater total body clearance of *R*-disopyramide compared to the *S* isomer may be explained by the lower plasma protein binding of the *R* isomer (13, 14). Also, the higher synovial fluid concentrations of *S*-ibuprofen following administration of the racemate appears to be related to the lower plasma protein binding of this isomer compared to that of the *R* isomer (15).

An unique example of stereoisomer selective tissue uptake of stereoisomers is noted with NSAIDs. The *R* enantiomer of ibuprofen shows preferential uptake into fat following the administration of the racemate and individual isomers (16). However, this apparent difference in fat distribution is probably a consequence of the selective metabolic uptake and formation of the coenzyme A thioester of the *R* isomer, which does not occur with the *S* isomer.

Drug Biotransformation

Numerous metabolic pathways involving mixed-function oxidases, esterases, transferases, and hydroxylases exhibit selectivity toward stereoisomeric substrates. Of all disposition differences that stereoisomers may display, the greatest stereoselectivity is expected in biotransformation, because of the specificity of metabolic enzymes and isoenzymes. The overall differences in hepatic clearance

of stereoisomers reflect not only differences in intrinsic clearance (activity of drug metabolizing enzymes) for the isomers but also the steric effects of plasma protein binding and hepatic blood flow.

When stereoisomers are biotransformed by a variety of pathways, differences in the susceptibility of the separate isomers to these pathways result in stereoselectivity for their metabolite patterns. For example, *S*-warfarin is oxidized to form primarily 7-hydroxy-*S*-warfarin, whereas the *R* enantiomer predominantly undergoes hydroxylation in the 6-position (17, 18). Oxazepam glucuronidation is 3–3.4 times higher for the *S* isomer compared to the *R* isomer in man and dogs (19). Biotransformation may generate an additional chiral center in the drug structure and result in diastereomeric metabolites with markedly different disposition characteristics.

Some of the greatest differences in the pharmacokinetics of stereoisomers can be attributed to stereoselective hepatic biotransformation. The oral clearance of *S*-mephenytoin is 170 times that of the *R* enantiomer in extensive metabolizers of the drug (20). This large difference in clearance is reflected in a 2-h half-life for the *S*-mephenytoin compared to a 76-h half-life for the *R* enantiomer in the same patient group. Interestingly, the half-life of the *S* isomer (63 h) and the *R* isomer (77 h) are similar in poor metabolizers of mephenytoin. Numerous other examples of stereoselectivity in hepatic clearance can be found in the literature (21–23).

Metabolic processes in humans and animals may invert the configuration of several NSAIDs. For many

2-arylpropionic acid NSAIDs in humans, the *S* enantiomer is the pharmacologically active form. Following administration of the racemate or *R* enantiomer, a slow inversion of the *R* to the *S* enantiomer occurs. All the 2-arylpropionic acid NSAIDs are administered as the racemate with the exception of naproxen. Based on investigations of ibuprofen, the *R* enantiomer is inverted to the *S* enantiomer via coenzyme A thioester formation (24, 25). It has been estimated, from pharmacokinetic studies of racemic ibuprofen that approximately 63% of the *R* isomer is inverted to the pharmacologically active *S* form (26). Stereoisomeric inversion is not universal for all 2-arylpropionic acids in humans with reports of inversion for ibuprofen, fenoprofen, and benoxaprofen and little or no evidence of inversion for tiaprofenic acid, ketoprofen, indoprofen, and carprofen (27–33).

Racemic drugs that experience hepatic “first-pass” metabolism of one or both isomers may experience stereoselectivity in biotransformation prior to the drug entering the systemic circulation, resulting in a route of administration effect on plasma concentration ratios and therapeutic response. Following IV doses of propranolol, plasma concentrations of both enantiomers appear to be similar, with only slight differences in total body clearance between the isomers (34). When propranolol is given orally, the higher rate of biotransformation and lower plasma binding of the less active *R* isomer results in lower plasma concentration of this isomer compared to the active *S* isomer. Other drugs administered as racemate such as verapamil, metoprolol, and prilocaine are reported to display stereoselective hepatic first-pass effects on the oral bioavailability of their isomers (35–38).

Renal and Biliary Excretion

The tubular secretory contribution to drug renal clearance has the potential of producing stereoselective renal elimination in the handling of stereoisomers. Enantiomers of terbutaline, disopyramide, and pindolol exhibit stereoselective renal clearance, probably due to differences in tubular secretion of individual stereoisomers (39–41). When examining the renal clearance of unbound disopyramide, the *L*-enantiomer has a renal clearance 29–86% higher than that of the *D*-isomer. The overall clinical significance of renal clearance differences for stereoisomers depends on the importance of renal elimination in the drug's total elimination. Biliary clearance of stereoisomers is difficult to evaluate in light of the techniques required and the many stereoselective factors influencing rate of biliary excretion. For these reasons, uncomplicated examples of stereoselective biliary excretion are not common.

Pharmacodynamics and Stereoselective Pharmacokinetics

The potency ratio (eudismic ratio) for stereoisomeric drugs reflects not only pharmacokinetic but also pharmacodynamic variations for the individual stereoisomers. In many respects, pharmacodynamic differences contribute more to large potency and activity differences of stereoisomers. Stereoselectivity at the level of drug-receptor interactions appears to be more pronounced than that noted for biotransformation or protein-binding interactions. A wide range of drug classes have been identified in which stereoselective pharmacodynamics are seen (4). Evidence for pharmacodynamic differences between stereoisomers is found in studies of isolated tissue and organ preparations and the relationships of drug response to plasma concentrations (42–44).

Analysis of pharmacological effects versus plasma concentrations of stereoisomers have been interpreted in terms of pharmacodynamic stereoselectivity. Pharmacological and toxicologic effects should be related to free plasma concentrations of stereoisomers in order to be able to appropriately compare activity or potency. Comparison of the free warfarin plasma concentration required to produce a 50% inhibition in synthesis of the prothrombin-activity complex reveals that *S*-warfarin has five times the inhibitory activity of the *R* isomer (45). The impact of the higher pharmacodynamic activity of *S*-warfarin on the dose-effect relationships of warfarin stereoisomers is partially offset by the fact that the *S* isomer is metabolically cleared more rapidly.

Pharmacokinetic Implications and Considerations

Recognizing that stereoisomers may vary markedly in their pharmacokinetic and pharmacodynamic profiles raises questions as to the usefulness of drug disposition, bioavailability, and pharmacodynamic modeling studies in which racemic forms are administered and nonstereospecific assays are utilized. Total body clearances, volumes of distribution, and bioavailability parameters become complex when the plasma concentrations of both stereoisomers are added. Clearance and bioavailability values observed after dosing of a racemic agent reflect a value falling between that of the two isomers (46–49). The observed half-life of the racemate is that of the stereoisomer with the longest half-life. The necessity of providing pharmacokinetic and pharmacodynamic data for both stereoisomers as well as their possible interaction could discourage the development of individual stereoisomers of drugs.

Since the administration of a racemate involves two separate drug entities, there can be intersubject variability in pharmacokinetic and pharmacodynamic profiles for both stereoisomers. Intersubject variability in the pharmacokinetics of both isomers leads to a large range of plasma concentration ratios across populations of patients. Factors such as disease, age, genetics, and concurrent drug therapy have been shown to lead to differing effects on stereoisomers of a drug. For example, the ratio of *S*- to *R*-tocainide plasma concentrations may vary over a 1.5- to threefold range (50, 51). *R*-Tocainide is believed to be several times more active than the *S* isomer (52). Factors such as disease, age, genetics, and concurrent drug therapy have been shown to lead to differing effects on stereoisomers of a drug. Liver disease patients have lower *S/R* ratios of plasma concentrations for ibuprofen stereoisomers than healthy subjects and this may be related to decrease conversion of the *S*- to *R*-isomer (53).

A major source of intersubject variability for stereoisomers is polymorphism in drug biotransformation (54). Extensive metabolizers of metoprolol display higher clearances of both stereoisomers than poor metabolizers, but the magnitude of the differences between stereoisomers is not the same within each population (38). Extensive metabolizers of metoprolol require lower total (*R* and *S*) plasma concentration of metoprolol for the same degree of beta blockade (51). In addition, *R*-mephenytoin shows similar oral metabolic clearance in extensive and poor metabolizers, whereas *S*-mephenytoin, which undergoes 4-hydroxylation, has markedly higher clearances in extensive metabolizers (55).

The area of clinical pharmacology that first directed attention to the consequences of stereoisomerism on therapeutic and pharmacokinetics was that of drug interactions, particularly those of the anticoagulant warfarin. Not only may drug interactions be stereoselective, but there is a potential for one stereoisomer to alter the pharmacokinetics and pharmacodynamics of the other. A classical example is the interaction with achiral phenylbutazone, which inhibits the metabolism of active *S*-warfarin but stimulates the metabolism of the less active *R* isomer (56). Other stereoselective drug interactions include the induced elimination of misonidazole by phenytoin (57). Phenytoin enhances the clearance of (4-)-misonidazole by 56%, which is higher than the increase in clearance of (-)-misonidazole.

Identical chemical and physical properties of enantiomers represent a potential source for enantiomer-enantiomer interactions at both pharmacokinetic and pharmacodynamic levels. Whether by competition for plasma- or tissue-binding sites or for drug-metabolizing enzymes, enantiomers may exhibit changes

in pharmacokinetics when administered as a racemate compared to individual stereoisomers. The enantiomers of disopyramide exhibit similar clearance and volumes of distribution when given separately (14). However, when administered as the racemate, the *S* isomer has higher clearance and volume of distribution. Ibuprofen enantiomers have also been shown to undergo enantiomer-enantiomer interactions (58).

In the past, pharmacokinetic and pharmacodynamic investigations of chiral drugs have neglected the influences of stereoisomerism. This is primarily a result of the lack of stereospecific analysis procedures. Nonstereospecific assays give pharmacokinetic and pharmacodynamic information which represents a complex combination of the characteristics of the separate stereoisomers. With the advent of stereospecific analysis procedures a better understanding of drug kinetics and action as possible.

ANALYTICAL METHODOLOGY AND ISOMERISM

A diastereoisomeric interaction is always required for the resolution of enantiomeric substances. This interaction occurs between the enantiomers of interest and a second enantiomeric species often referred to as the chiral selector. The diastereoisomeric interaction between the enantiomers and the chiral selector may involve a covalent bond or other less stable noncovalent associations. In the example below, a mixture of *R* and *S* isomers associates with the *R* isomer of the chiral selector to yield two diastereoisomeric products:

In this process, enantiomers (*R* and *S*) of the heterochiral substance of interest interact with the homochiral selector (*R*) to yield two products having a diastereoisomeric relationship. The formation of diastereoisomeric complexes is the basis for enantiomeric separations. The ability to use smaller differences in the rates of formation, stability, and properties of these complexes has been responsible for the major advances in stereochemical separations.

Chromatographic Techniques

The chromatographic separation of enantiomers, often referred to as enantioseparation, has received a great deal of attention in recent years. Both liquid (LC) and gas (GC) chromatographic procedures are used. The former is

extremely useful for enantioseparations because of the available variations in scale, mechanism, and technique. It has been used in enantioseparations from analytical to preparative in scale, taking advantage of various modes of diastereoisomeric interactions and using elution and displacement techniques. All the chromatographic methods involve diastereoisomeric interactions between the enantiomers of interest and a second chiral substance, the chiral selector. The difference in the interaction of the two enantiomers with the chiral selector is the enantioselectivity, $\alpha = k'_R/k'_S$; it can be thermodynamic or kinetic in nature. The choice of k'_R or k'_S as the numerator of the enantioselectivity expression is made for a ≥ 1.0 . The k' (capacity factor) is defined in the customary manner in Equation (6).

$$k' = (V_R - V_0)/V_0 \quad (6)$$

It represents the number of column volumes required to elute the enantiomer. The volume of mobile phase required to elute the component V_R (the elution volume, retention volume) and the void volume, V_0 , are the chromatographic measurements needed to calculate the capacity factor. The void volume is defined as the volume of mobile phase required to elute an unretained solute.

Chromatographic enantioseparations can be achieved when the diastereoisomeric interaction is established via a precolumn covalent derivatization, or a noncovalent association formed within the chromatographic system through the use of chiral mobile phase additives (primarily an LC technique) or chiral stationary phases.

PRECOLUMN DERIVATIZATION

The reaction of a homochiral derivatizing agent with a heterochiral sample to yield covalently linked diastereoisomeric products is a precolumn technique used for the analysis of the individual enantiomers. The diastereoisomeric products are separable under a variety of chromatographic conditions (GC and LC), including both normal and reversed-phase procedures (59–61). Fig. 23 shows the LC separation of two diastereoisomeric products formed by the reaction of a heterochiral amine and a homochiral derivatization reagent. The derivatization reaction involves the formation of an amide by treating an *N*-substituted *S*-prolyl chloride with racemic amphetamine (Fig. 24).

The configuration of the asymmetric center in the prolyl moiety is homochiral *S* and the racemic amphetamine (*R* and *S*) yields diastereoisomeric amides *S,R* and *S,S*. Thus, these amides have the same configurations (*S*) at the center

Fig. 23 Normal-phase liquid chromatographic separation of 4-nitrophenylsulfonyl-*S*-prolylam-phenetamine. 1 = *R*-amphetamine, 2 = *S*-amphetamine. (Ref. 60.)

Fig. 24 Precolumn diastereomeric derivatization.

Fig. 25 GITC derivatization of a primary amine.

originating from the prolyl moiety, and differing configuration at the chiral center originating from heterochiral amphetamine. A similar derivatization procedure with *N*-trifluoroacetyl-*S*-prolyl chloride is used in GC to form diastereoisomeric amides. The *N*-TFA moiety imparts volatility and electron capture detectability to the derivatives for GC analysis (62).

The homochiral derivatization reagents are usually modified compounds that are available in high

enantiomeric purity. Cost and availability make naturally occurring substances such as amino acids excellent sources of enantiomeric purity. A reagent widely used in the diastereoisomeric derivatization of amines is 2,3,4,6-tetra-*O*-acetyl-13-D-glucosyl isothiocyanate (GITC) (Fig. 25). The isothiocyanate moiety reacts with primary and secondary amines yielding thiourea products, thus covalently linking the homochiral acetylated glucose and the amine (63). If the amine is racemic, the products are a diastereoisomeric pair. The configurations of all the chiral centers in glucose remain the same and the two configurations in the amine yield diastereoisomeric products (60). Fig. 26 shows the reversed-phase LC separation of diastereoisomeric ureas following derivatization of a racemic amine sample with GITC.

Mobile-Phase Additives

The direct separation of enantiomers by chromatography can be achieved by two fundamentally different processes: The diastereoisomeric interaction can occur between the sample molecules and the stationary phase or between the sample and chiral mobile-phase additives. Consequently, two different results can be obtained: A chiral stationary phase with an achiral mobile phase or an achiral stationary phase with a chiral mobile phase. The use of chiral mobile-phase additives is limited to LC procedures. The most widely applied examples include ligand exchange, ion-pair and inclusion complexation.

The exact sequence of events in the case of chiral mobile-phase additives varies, depending on the affinity of the additive for the achiral stationary phase. The chiral additive may associate with the stationary phase to become a dynamic chiral stationary phase, or the additive and sample molecules may form a diastereoisomeric complex in the mobile phase which associates with the achiral stationary phase.

Cyclodextrins

The cyclodextrins are perhaps the most widely used mobile-phase additives which form diastereoisomeric inclusion complexes. The cyclodextrins (α , β , and γ -cyclodextrins) are made up of α -D-glucose units (6, 7, or 8 α -D-glucose molecules) cyclized to form a truncated cone-like molecule (Fig. 27). The interior cavity of this molecule contains hydrogens and glycoside oxygens and is relatively lipophilic, whereas the exterior of the cyclodextrin molecule is composed primarily of hydroxyl groups and therefore is relatively hydrophilic. The wider end of the cone is composed of secondary hydroxyl groups and the narrow (truncated) end is composed of the primary

Fig. 26 Reversed-phase liquid chromatographic separation of GITC-derivatized amines. 1 = *R,R*-pseudoephedrine, 2 = *S,S*-pseudoephedrine, 3 = *R,S*-ephedrine, 4 = *S,R*-ephedrine, 5 = *S*-methamphetamine, 6 = *R*-methamphetamine. (From Ref. 61.)

Fig. 27 Structure of α -cyclodextrin.

hydroxyl groups from the individual D-glucose units. Thus, complexation reactions occur only from the secondary OH side. The dimensions of the cavity in the cyclodextrin depend upon the number of glucose units in the compound.

The cyclodextrin-solute inclusion complexation is a reversible reaction with an equilibrium constant similar to that for diffusion-controlled processes. Thus, the effect of underivatized cyclodextrins as mobile-phase additives is often a reduction in column efficiencies. The increase in peak width in cyclodextrin systems compared to that of conventional reversed-phase systems requires a decrease in flow rates for best resolution. Some enantioseparations using this technique report flow rates between 20 and 40 $\mu\text{l}/\text{min}$ (64). Considerable column efficiency changes occur over a flow range of 0.02–2.0 ml/min. In addition to flow rate, the concentration of cyclodextrin in the mobile phase can be adjusted to optimize enantioseparations.

The pH, temperature, and ionic strength of the mobile phase also affect the cyclodextrin-solute complexation and retention properties. Many enantio-separations using cyclodextrin-modified systems involve solutes with an aromatic ring substituent or similar cyclic structure at the chiral center. A variety of chiral barbiturates, hydantoins, and related compounds (65–67) have been resolved by using β -cyclodextrin and alkylated B-cyclodextrin-modified systems.

Ligand Exchange

The ligand-exchange process has been applied as a mobile-phase-additive technique for enantioseparations.

Fig. 28 Diastereoisomeric chelates.

It involves the formation of a dissociable diastereoisomeric complex between a homochiral additive and a heterochiral solute about a central metal ion (Fig. 28). The mobile phase contains both the homochiral ligand and the metal ion as additive components. These species probably exist as the fully complexed species with at least two molecules of the homochiral additive complexed to the metal ion. The ligand exchange with the components of the heterochiral sample enantiomers yields diastereoisomeric products. Obviously the concentration of the homochiral additive ligand is relatively high compared to the heterochiral sample molecule. Thus, the probability of displacing two molecules of homochiral ligands from the metal ion is extremely small, limiting the number of possible products to just two, as seen in Equation (6).

where HoL, is the homochiral ligand; HeL, is the heterochiral ligand, and; M, is the metal.

Ligand exchange has found extensive use in the resolution of amino acids, amino acid derivatives, and other bidentate ligands (68, 69). These separations are done using an aqueous or organic modified aqueous mobile phase in which the metal ion, such as copper(II) from copper sulfate, is soluble. The stationary phase is usually a hydrocarbon such as C_8 . Some of the widely used homochiral ligands such as L-proline and L-hydroxyproline (70) are N-alkylated with large hydrocarbon moieties such as C_8 to enhance the dynamic chiral stationary-phase process. The hydrocarbon moieties of the ligand and the stationary phase associate in the usual solvophobic process, leaving the chelating functional groups exposed to the mobile phase and its components.

The mobile-phase-additive ligand-exchange chromatography has been applied to the resolution of some chiral amino alcohols. The enantiomers of norephedrine, norpseudoephedrine, metaraminol, and phenylephrine were resolved (70) in a reversed-phase procedure using a 0.05 M acetate buffer mobile phase containing N-octylhydroxyproline and 5–8 mM copper(II). All these enantioseparations show base-line resolution

Fig. 29 Ligand-exchange liquid chromatographic separation of norephedrine (A) and norpseudoephedrine (B), using a C_{18} stationary phase coated with *N-n*-dodecyl-L-hydroxyproline and a mobile phase containing 5 mM copper(II). (From Ref. 72.)

with norpseudoephedrine (Fig. 29), yielding an enantioselectivity in the 2.0 range ($\alpha = 2.0$) and the 1S, 2S-isomer eluting before the 1R, 2R-enantiomer.

Diastereoisomeric Ion Pairs

The addition of a homochiral counterion to the mobile phase for the LC resolution of enantiomers can yield enantioseparations with only slight differences in the properties of the resulting diastereoisomeric ion pairs. Derivatives of L-proline and 10-camphorsulfonic acid have been used to resolve enantiomeric amines through the formation of diastereoisomeric ion pairs (71). The concept of reciprocity in these separations (72) has been shown to occur in such a way that if the *R* enantiomer of acid HA resolves base B into its *R*- and *S*-enantiomers, an enantiomer of B (for example, *R*-B) can be used to resolve *R*-HA and *S*-HA.

Chiral Stationary Phases

The use of chiral stationary phases (CSP) in liquid chromatography continues to grow at an impressive rate. These CSPs contain natural materials such as cellulose and starch as well as totally synthetic materials, utilizing enantioselective and retentive mechanisms ranging from inclusion complexation to π -electron interactions. The major structural features found in chiral stationary phases include cellulose, starch, cyclodextrins, synthetic polymers, proteins, crown ethers, metal complexes, and aromatic π -electron systems.

Fig. 30 Cellulose (XH) and derivatives.

Cellulose and Starch

Cellulose and starch are naturally occurring polysaccharides exhibiting enantioselective properties. Cellulose is a linear polymer of D-glucose units with individual fibers arranged in parallel bundles through hydrogen bonding between the fibers (Fig. 30). Starch is a similar material, containing a higher degree of branching with enantioselectivities similar to those of cellulose. The mechanism of retention and enantioselectivity for cellulose involves hydrogen bonding and possibly the formation of inclusion complexes within the cellulose structure. The chromatographic procedures used for these materials involve normal-phase conditions (nonpolar solvents), which allow for strong hydrogen-bond formation between the solute and CSP. A variety of stationary phases of varying enantioselective and retention properties have been prepared by chemical modification of the hydroxyl groups by esters, nitrates, carbamates, and ethers. Because of their excellent chiral recognition properties, these materials have been used to resolve a large number of pharmaceutically significant compounds (73).

Synthetic Polymers

Synthetic polymers can be prepared to contain chirality as is the case for cellulose and other natural polymers. Chirality can be introduced into the monomer before polymerization to yield the chiral polymer. Alternatively polymerization of an achiral monomer in the presence of some chiral catalyst yields the chiral polymer. Poly-methacrylates exhibiting chirality due to single-handed helicity have been prepared via polymerization in the

Fig. 31 Crown ether complexes.

Fig. 32 3,5-Dinitrobenzoylphenylglycine (DNBPE) stationary phase.

presence of a chiral catalyst. These materials are used in liquid chromatography primarily under low-pressure conditions and have shown good resolution for compounds capable of hydrogen-bond formation.

Proteins

Proteins are naturally occurring chiral polymers that interact selectively with chiral solutes. The proteins most widely used as chiral selectors in liquid chromatography are albumin and α_1 -acid glycoprotein. These proteins are covalently linked to silica particles and are used primarily in the reversed-phase mode of separation.

Bovine serum albumin has a molecular weight of about 6.6×10^4 and consists of 581 amino acids. The tertiary structure of the protein is controlled by the 17 disulfide linkages, and at pH 7.0 the net charge on the protein is -18 . The human plasma protein, α_1 -acid glycoprotein, contains five carbohydrate units and has a molecular weight of 4.1×10^4 . The 14 sialic acid residues in the sugar units are involved in binding various cationic species and are believed to play a role in the chiral selectivity of this protein.

The mechanism of solute retention and chiral recognition is similar for both albumin and α_1 -acid glycoprotein and involves charge and dipolar interactions in addition to hydrophobic associations. The mobile-phase variables that can be adjusted to affect retention and chiral recognition include pH, ionic strength, and organic modifier (74). Such changes affect the properties of the solute as well as the stationary-phase protein. Thus, pH changes can alter the retention of a neutral solute by changing the properties of the binding site on the CSP.

Crown Ethers

These macrocyclic ethers assume a crown-like shape in solution with a central cavity capable of containing a small solute. They bind to small cationic species through association with the electron-rich oxygens of the ether

linkage. Chiral crown ethers (Fig. 31) serve as selectors for enantiomeric amines in the protonated state (75). They have been used as mobile-phase additives and been covalently linked to the surface of silica particles. The chromatographic procedure for these materials is primarily the reversed-phase mode, and many separations are done in a purely aqueous mobile phase modified to pH 1–2.0 with perchloric acid.

Chiral recognition in these phases is achieved when a chiral center is introduced into the crown ether to serve as a barrier to one enantiomer of the guest amine. The chiral barrier is usually a large bulky group that selectively affects the association of one enantiomer of the amine.

Aromatic π -electron Systems

These CSPs have in common a strong aromatic π – π interaction, dipolar stacking process as a central component of the retention process. They are often referred to as Pirkle columns based on the pioneering work by Pirkle and coworkers (76, 77). These π -donor and π -acceptor interactions occur though the tendency of some electron-rich aromatic systems to donate π -electrons (π -base) to an electron-deficient acceptor aromatic system (π -acid). These CSPs offer the clear advantage of complete structural characterization of the stationary phase. Since these are totally synthetic phases prepared by linking small chiral substances to silica particles, all the solute-stationary phase interactions can be readily predicted. The solute-CSP interactions include hydrogen bonds, steric, dipole–dipole, and conformational as well as π – π interactions. These phases generally consist of an acylated amino acid covalently linked to aminopropyl silica (Fig. 32). The acyl group is usually an aromatic acid, with the π acceptor 3,5-dinitrobenzoyl group among the most common. Phenylglycine and leucine provide chirality of general utility for the resolution of many chiral substances.

The major advantage of these phases is the ability to manipulate structure and the reciprocity of chiral recognition. The reciprocity approach is not readily available for the naturally occurring polymeric CSPs

such as cellulose, proteins, and others. Those solutes not containing the complementary π -acid or π -base functionality can often be derivatized to incorporate these features into the molecules of interest.

ISOLATORS FOR PHARMACEUTICAL APPLICATIONS

Gordon J. Farquharson

Bovis Lend Lease Pharmaceutical, United Kingdom

INTRODUCTION

The use of isolators in research and manufacturing in the health care and life science industries continues to develop rapidly. An overview shows many new applications being conceived, designed, constructed, and set into operation to satisfy many different processing needs. These applications frequently fall outside the accepted concepts and practice found in human scale rooms. It is only in the last 2 or 3 years that the technology has been recognized within cGMP guidelines and regulations. This article attempts to describe the practical experience gained from consultancy and design of isolators from the early 1970s up to and including state of the art applications developed today. For clarity, an isolator can be defined as:

A device creating a small enclosed controlled or clean classified environment in which a process or activity can be placed with a high degree of assurance that effective segregation will be maintained between the enclosed environment, its surroundings, and any personnel involved with the process or manipulation. Isolators can be closed or open designs, and may be maintained at positive or negative pressure to their surroundings.

The following list summarises some essential features that help to expand on the definition as it is applied in the life science and pharmaceutical industry context:

- An isolator is an enclosed controlled environment of minimum volume.
- Isolators segregate people from processes.
- Isolators can contain processes hazardous to the surroundings, processes that are at risk from the surroundings, or in some cases activities where both types of risk coexist.
- Isolator walls or envelopes may be rigid or flexible; typical primary materials are stainless steel and glass, and polyvinyl chloride (PVC) flexible sheet welded to form an enclosure.
- Isolators are internally pressurized with air or inert gas to help achieve the required segregation between inside and outside. Pressurization can be positive or negative.

- Air filtration through High Efficiency Particulate Air (HEPA) or Ultra Low Particulate Air (ULPA) filters (9) is used to control the quality of air entering, leaving, and recirculating. For some applications in which very small inert gas quantities are used, nitrogen, for example, can be delivered through sterilizing-grade membrane filters.
- Isolators are frequently connected intimately to items of process equipment to provide an effective locally controlled environment.

The principal industry drivers generating the interest in isolators in the last few years have been focused on improvements in process integrity. This includes operator protection from potent and hazardous materials and, in the case of sterile products manufacturing, to reduce the potential of contaminated nonsterile units from being produced by a specific process. There are some circumstances in which reductions in occupied space and operational cost savings have been essential objectives.

TECHNICAL GUIDELINES AND STANDARDS

Although guidelines, such as the UK Pharmaceutical Isolator Guideline (1), and standards for microbiological safety cabinets (2, 3) and those for flexible-film isolators (4), satisfy part of the need for effective standards, further support is needed. During 2001, the ISO Technical Committee 209 should publish EN/ISO (DIS) 14644-7 (5). This standard will be entitled "Enhanced Clean Devices." Although it is not pharmaceutical industry specific, it will contain much excellent basic good practice guidance. 2001 should also see publication of PDA's Monograph "Design and Validation of Isolator Systems for the Manufacturing and Testing of Health Care products." Useful sources of reference can also be obtained from the nuclear industry. ISO 10648 "Containment enclosures" contains some valuable sections (6, 7).

For isolators, the barrier between the critical controlled environment and its surroundings is created by a single element, rather than the multilayer protection approach used in cleanroom technology. It is essential, therefore, to realize that the engineering solution, integrity, and

reliability of the final operational isolator will have a direct impact not only on the enclosed process, but also on the quality required of the surrounding environment. This is particularly so when an isolator is used to contain a vulnerable aseptic process. This is usually be the most critical task for isolators, and the one that is most difficult to prove.

The design and construction of isolators should be carried out in an appropriate quality-assured way because the devices are frequently complex and require a high level of documentation to comply with both safety and good quality requirements. ISO 9000 compliant or similar quality assurance systems provide an appropriate management environment in which to design and build systems destined for quality or safety critical applications.

HEALTH CARE INDUSTRY REGULATORY DEMANDS AND EXPECTATIONS

Many operational applications are now in place, particularly in Europe. They can be found in manufacturing, R&D, and QC sectors. Experience continues to develop, and the users are at the forefront of the knowledge. Regulatory guidance can now be found in the European Union Guide to Good Manufacturing Practice (EU GMP) and will shortly appear in "Pharmaceutical Inspection Co-operation Scheme" (PICS) inspection guidelines. It is the responsibility of the isolator user, together with the designer or supplier, to effectively demonstrate an appropriate level of system integrity and performance. Regulators primarily hope to see that the use of isolators has been targeted at improvements in sterility or other attributes of quality assurance, as well as operator health and safety, and environmental protection. Such regulators may be less impressed by issues relating to reduction of unit manufacturing cost or amount of capital employed.

At present, the pharmaceutical industry regulatory requirements refer to isolators specifically in the context of the manufacture of sterile products. There is no reference to their role in broader areas of crosscontamination and operator safety control. Within Europe, the current EU GMP clearly states that isolators might produce improvements in sterility assurance of sterile products, and that aseptic processing manufacturing isolators should be placed in at least a Grade D surrounding environment. The Food and Drug Administration (FDA) requirements are less well defined, but it is likely that in equivalent circumstances, they would like to see an isolator located in a class 100,000 or M6.5 environment "In Operation."

As far as the configuration and performance of isolators is concerned, the pharmaceutical regulators have not made specific demands in their documentation. However, some of the main issues that have been identified by U.S. and European investigators or inspectors include:

- Concern that the use of isolators engenders a false sense of security, and that cGMP standards might be abandoned
- Concern over the effects of vibration caused by the process and the critical environment being physically connected
- Integrity of glove and half-suit systems
- Effective leak testing regimes that should be established
- Effectiveness of the physical cleaning of isolators applied in conjunction with gaseous or aerosol disinfection systems
- Evidence of good ergonomic design
- A well-defined and implemented personnel intervention policy, including intervention recording
- Tailored process simulation programs for aseptic processing
- Inappropriate sterility assurance level claims

APPLICATIONS

Isolator systems can be used for quality-critical, safety-critical, or combined applications. The examples given here are not exhaustive but focus on some of the most important applications, and clearly illustrate the broad range of devices that are created to satisfy particular needs.

Sterility Testing

For many years, isolators have provided a valuable tool for providing very clean conditions in the microbiological laboratory for testing the sterility of the end product. Both flexible-film and rigid-wall devices have been successfully utilized. These isolators are used to carry out manipulations with a growth-promotion medium. Any failures in the security of the isolator are likely to manifest themselves as growth in the culture medium. Such growths would be deemed false positives, and would result in a requirement to investigate the source of contamination. The security and effectiveness of isolators, operating in conjunction with sanitization techniques and transfer systems such as interlocking transfer ports, have been demonstrated to provide a more secure system than the traditional cleanrooms for this type of analytical work.

Sterility testing requires a strict control of microbial contamination challenge from outside the controlled environment, but not of the particulate contamination liberated by the process itself. Hence, a positive-pressure isolator in a controlled environment, using nonunidirectional airflow, is satisfactory. Flexible-film devices using half-suit manipulation techniques are frequently used in these applications. These isolators are usually configured as "closed" isolators because they don't have continuous-process discharges from the contained

volume. Fig. 1 shows an example of an isolator used in sterility testing.

Subdivision and Dispensing of Potent Compounds

As pharmaceutical products contain increasingly potent active constituents and as health, safety, and environmental protection issues increase in importance, isolators have been developed in many shapes and forms to permit

Fig. 1 Flexible-film isolator with half-suit used for sterility testing. (Diagram courtesy of La Calhene.)

Fig. 2 Potent drug-dispensing isolator. (Photograph courtesy of TPC Microflow Ltd.)

the safe weighing and subdivision of highly active compounds. The most sophisticated applications, such as the subdivision of bulk sterile active compounds, require that the isolator maintain aseptic processing conditions internally at the same time as satisfying the

safety requirements. Fig. 2 shows an isolator device designed to allow a keg of potent raw material to be introduced into an isolator environment, and be securely subdivided into lots suitable for a subsequent formulation batch process. The device includes systems for mechanical

Fig. 3 Specialized isolator for potent drug processing and handling. (Photograph courtesy of TPC Microflow Ltd.)

handling of the kegs, and for washing their exterior to decontaminate them after completion of the manipulation.

Powder Processing Systems

A natural extension from the simple handling of potent compounds is to use barrier technology to provide highly secure mechanisms for processing and more complex manipulation of powders. Isolators of this type and configuration have the objectives of operator and environmental protection as well as the provision of a secure clean and aseptic environment around the process.

The example shown in Fig. 3 is a system used for the drying and handling of bulk powder. It provides a clean classified environment for handling bulk powder, a containment of the potent compound, and a nitrogen environment to allow the safe use of flammable solvents. It is a rigid positive-pressure device located in a EU GMP Grade D cleanroom. The cleanliness of the internal nitrogen environment is maintained using nonunidirectional airflow. Manipulations are achieved using a combination of glove and half-suit systems.

Small-Scale Manipulations

Many isolator applications at the clinical trial scale of manufacturing are based on the same scale of technology used for sterility testing. The aseptic dispensing of pharmaceutical products in hospital pharmacies is also carried out on this scale. Such manufacturing is not carried out on a continuous basis, but in relatively small batches

that can be transferred from the isolator with the help of one of the more secure transfer systems. In this type of application, one isolator is being used to dispense a variety of products or several isolators are used for separate tasks.

In the application shown in Fig. 4, a group of isolators are placed in an EC Grade C working environment (approximately equivalent to ISO 7 or Class 10,000 "At Rest"). The isolators are configured to provide an aseptic environment interfacing with a depyrogenating oven for handling and holding dry-heat-sterilized components. Additional individual isolators are provided in which separate formulation and/or filling operations can be undertaken. Materials are moved from one isolator to another using closed containers that dock with alpha/beta docking ports mounted in the sidewall and floor of the isolators. Internal cleanliness is maintained through positive pressurization and the supply of double HEPA-filtered unidirectional airflow to the critical process zones within the isolators.

LARGE-SCALE ASEPTIC PRODUCTION

Isolators are now used in industrial scale aseptic processing for both formulation and filling. Fig. 5 shows an example of a rigid interconnected network of isolators providing a complete component handling and aseptic filling capability in an integrated line. The internal control of the environment is achieved by a combination of nonunidirectional and unidirectional airflow within positively pressurized cells. The individual cells are

Fig. 4 Isolators used in clinical trials and specials manufacturing (the gloves have been removed for photographic clarity). (Photograph courtesy of Boots Contract Manufacturing and Bovis Tanvec Ltd.)

separated by “airlock” flap valves. The product flow through to aseptic filling operations is largely automatic, with gloves provided for specific manual interventions. The complete line is placed in a room in which the environment is controlled but unclassified in terms of cleanroom standards. Hydrogen peroxide vapor is used for the surface sterilization of the isolator network, and for the continuous surface disinfection of containers of product components that enter the system.

Technical Considerations for the Design, Manufacture, and Testing of Isolators

The susceptibility of the process to contamination is critical in terms of risk assessment. In aseptic processing, for example, open processes are at far greater risk than closed processes. Furthermore, systems requiring complex aseptic assembly prior to use are more difficult to manage in a small isolator environment than if cleaning and sterilization-in-place techniques were employed (referred to as *CIP* and *SIP*). It is essential, therefore, to evaluate all the process steps, including equipment transfers, assembly manipulations, and the processing activity itself. Effective documentation of such analysis is good practice in a validated operational scenario.

Barrier-integrity characteristics

Complex isolators are unlikely to be leak free. It is obvious that the better the barrier integrity is, the less will be the

opportunity for contamination to be transferred across the isolator wall. The integrity is influenced by the basic materials of construction, design effectiveness, damage caused by cleaning, resistance to process chemicals, and robustness. The first fundamental option to consider is a rigid or a soft-wall construction. The former normally utilizes a combination of stainless steel and glass or Perspex windows; the latter uses a welded transparent PVC envelope connected to a stainless steel floor tray or machine bedplate. After choosing either a rigid or soft-wall solution, it is most important to ensure that an effective mechanism is selected to measure the leakage-air tightness of the isolator. Such tests should form part of the construction acceptance testing of a device, and should become part of routine operational leak testing. A pressure-hold test is the simplest method of determining that the complete assembly satisfies a set of acceptance criteria. Provided that the isolator, including its internal and external air systems, is configured in an appropriate way, simple isolating valves can be used to isolate the isolator, thus allowing convenient leakage-rate tests to be carried out. Such tests could ultimately be carried out on a batch basis if required. The most commonly used test methods are:

- Evaluation of pressure decay rate
- Leakage-rate measurement at constant pressure
- Tracer gas leak-rate detection
- Tracer particle transfer measurement (sometimes called a leak-induction test)

Fig. 5 A specialized network of isolators used for large-scale industrial syringe filling; process flow is from left to right. (Photograph courtesy of Medeva Ltd.)

Table 1 illustrates a range of four “Leakage Classes” that will be included in the “Enhanced clean devices” standard, EN ISO (CD) 14644-7. These classes are based on levels of leakage defined in the ISO 10648 (6,7) nuclear containment standards.

Manipulation technique

The manipulation technique influences the overall integrity of an isolator system, as in virtually all cases, the manipulation device presents a potential breach to the barrier of the isolator. Additionally, where the

manipulation involves placing part of the human body within a specialised system component, such as gloves or a half-suit, a greater potential exists for process or product contamination than would occur with tong manipulators, remote manipulators, or robotics devices. Utilizing a simple pressure-hold or leakage test on a glove port and glove before and after a process work session can achieve a high level of glove integrity assurance. Such a technique is virtually impossible with half-suit applications due to their size and construction. Strategic inspections and pressure tests for integrity at

Table 1 Isolator leak rates (tentative levels)

Leakage class reference	Leak rate enclosure air change/hour	Leak rate: percentage enclosure volume/hour %
1	$<5 \times 10^{-4}$ (<0.0005)	<0.05
2	$<2.5 \times 10^{-3}$ (<0.0025)	<0.25
3	$<10^{-2}$ (<0.1)	<10
4	$<10^{-1}$ (<1.0)	<100

less frequent intervals are required for such devices. Alternative manipulation methods using tongs and remote manipulators (mainly for handling radioactive substances) can be of advantage in isolators, but currently are rarely found in pharmaceutical applications. However, it should be noted that tong manipulators, for example, have their own special problems and use a gaiter system to ensure air pressure integrity around the rotation and sliding gimbals. This gaiter is akin to the glove gauntlet, and its integrity and risk of failure are just as important.

Manipulations should always be minimised. An event report should be made, and a preprepared action plan must be implemented should damage occur to a glove. The selection of glove and gauntlet materials is most important. Half-suit and sleeve/glove systems use a technique where the glove can be detached from the sleeve by way of a specialized fitting in the wrist region. Some of these devices have the capability of allowing glove change while the system is in use. Gauntlet or one-piece systems are generally more durable, but do not have the same change in use capability. A balance has to be maintained between durability and "feel." Typical available materials are:

- Latex (natural rubber) allows great dexterity; if thick enough, these can be wear and abrasion resistant. It is chemically resistant to many mild chemicals, detergents, and disinfectants.
- Neoprene (synthetic) has high flexibility and allows good dexterity. It has low tensile strength, and is chemically resistant to materials with the exception of oxidizing agents such as hydrogen peroxide.
- Nitrile (synthetic copolymer) has poor flexibility, but is strong and highly chemical resistant.
- PVC (synthetic polymer) is strong and chemically resistant to materials except ketones and aromatic hydrocarbons; it is inflexible and subject to tearing.
- Urethanes have good abrasion, chemical resistance, and good tensile strength, but are not suitable for high temperatures.
- Laminated polymers exhibit high strength and selective resistance to chemicals; they are subject to failure when used with sharp objects.

A variation of the pressure-hold test can be used to test the integrity of manipulation gloves in situ. This provides a convenient way of determining the integrity of the glove without entering the controlled environment or unnecessarily changing an expensive commodity. An alternative, provided by a particular vendor, involves inert gas purging of a glove volume, followed by measurement of the build-up of oxygen that diffuses through glove pinhole leaks.

Transfer techniques

The transfer of materials into and out of an isolator represents the most likely and most common source of loss of internal environmental integrity. The more secure the transfer system, the less demanding is the surrounding environment. The simplest devices, such as single doors, present very little ability to separate the external from the internal environment. In fact, in these applications, the only facet of the device's performance that provides any protection is outward airflow when the door or cover is open. Security can be improved by a double-door pass-through hatch. The performance and effectiveness of such a device can be improved by introducing mechanical or electromechanical interlocking of the opposing doors. Furthermore, adding positive ventilation of the airlock space to dilute and remove contamination that may enter when the external door is open adds security to this form of transfer. The most secure techniques include a direct process connection to the isolator, interlocked docking port systems (often called alpha/beta systems), and airflow protected tunnels for continuous component discharge. Although no specific tests or standards exist to define the performance of such devices, tests can be adopted from other applications. Containment tests such as those used for open-fronted microbiological safety cabinets can be effectively used to determine a protection factor for airflow-protected product-discharge tunnels. In the case of alpha/beta interlocked docking port systems, certain manufacturers have developed and applied particulate and microbiological challenge tests to determine the effectiveness or a protection factor of these devices. This quantifies the segregation achieved by such a device in operation. Such tests may become the basis of type or performance testing and subsequent selection of specialized transfer devices. A typical alpha/beta port is illustrated in Fig. 6.

Internal pressurization

Internal pressure within an isolator clearly has a major influence on the ability of the isolator to exclude the external environment. The level of the pressurization should also be considered in relation to its ability to withstand the piston effect of rapid glove movement, and whether or not the internal isolator air system should achieve a specific outflow of air in the event of partial or total glove loss. The integrity and performance of pressurisation equally apply to negative-pressure systems. However, negative-pressure systems, used for clean and aseptic processing, are more likely to require a higher class of surrounding environment than that required for equivalent positive pressure systems. The glove piston

Fig. 6 A typical alpha/beta port. (Illustration of DPTE courtesy of La Calhene.)

effect is relative volume related (i.e., the volume displaced by the glove compared to the volume of the isolator). As a rule of thumb, devices with a pressure of 15–25 Pa compared to the surrounding atmosphere, are likely to be less secure (due to the piston effect) than devices with a pressure of 50–80 Pa compared to the surrounding area. When lost glove airflow protection is required, air velocities of 0.5–0.7 m/s should be considered. If extremely high velocities above these figures occur, reentrainment of external contamination due to high turbulence is a distinct possibility. In testing the effectiveness of the pressurisation, it is necessary to challenge not only the steady state conditions but also the transient conditions. It is therefore expected that a series of tests be carried out to investigate start and stop modes of the isolator control system, the influence of glove or other device manipulation, and of course, the interaction of the process itself. The most demanding processes in aseptic pharmaceutical applications are usually continuous depyrogenation tunnels, where the air leakage into the tunnel due to isolator overpressure, varies with time, and may well vary with different machine settings for various sizes. In this type of application, it is absolutely critical that the qualification of the isolator environment

is carried out in conjunction with all states of operation. Similarly, it is essential that the depyrogenation process in the tunnel is fully qualified with all states of the isolator.

Airflow configuration

As with cleanroom applications, isolators can use unidirectional or non-unidirectional airflow regimes, or in larger systems a combination of both. Isolators are very different from cleanrooms in that generally a physical barrier separates critical from noncritical zones rather than the use of managed airflow. It is possible therefore in isolators to obtain the necessary levels of environmental cleanliness with very low air velocities. Unidirectional airflow systems designed to achieve class 100/M3.5/ISO 5 cleanliness can be achieved with velocities as low as 0.10 m/s. When the velocity is set at such low levels, it is necessary to carefully evaluate the influence of heat sources and process disturbance. Having defined the airflow characteristics required for the isolator, it is necessary to determine both the airflow rate using flow anemometers and the uniformity of the airflow in the case of unidirectional airflow systems. The latter is best achieved using flow visualization smoke-tracing

techniques. This is particularly important if an isolator environment itself contains a mixture of unidirectional and turbulent and/or conventional flow zones.

Filtered-air exchange rate in nonunidirectional flow systems should be based on the rate required to dilute internally generated contamination. The contamination decay rate of an enclosed volume can be used as a measure of effectiveness of the air-movement system in an isolator. This can be helpful for assessing the degassing rate at the conclusion of a gaseous sanitisation or sterilizing procedure. The decay rate can be measured using artificial aerosol generation combined with measuring the decay profile broadly in accordance with the method set out in IES recommended practice 006.2. Alternative gas-decay methods can be adapted from tracer-gas methods used to prove the effectiveness of ventilation systems.

HEPA filtration

The provision and location of air filters and the filtration integrity in isolators are as important as in clean or containment room technology. The filter and its installation must be designed with the utmost care, and special consideration should be given to the effect of vibration transferred from the isolator mechanical systems or the process. Final filters should be placed as close as possible to the critical zone. However, this sometimes makes the task of fitting the filters difficult due to restricted space and access. Maintenance convenience can be improved by locating filters close to, but away from the critical zone, in carefully engineered housings. When this technique is used, the duct between the filter and the isolator should be constructed of non shedding materials. Natural or artificial aerosol challenge tests are the appropriate way to test in situ final HEPA or ULPA filters and existing cleanroom oriented standards, and requirements are directly relevant to isolator applications.

Airborne cleanliness classification

Classification of the working environment by measuring the particulate concentration is normally carried out in accordance with the requirements stated within the accepted airborne-particle classification standards. If the isolator working volume is extremely small, it may be necessary to increase the number of test locations from the single point determined by using the formula within the standards. Two, three, or more locations focused on the critical points of process or product exposure. When continuous or cyclic automatic particle monitoring is being considered, care should be taken to ensure that the volume of air taken as a sample does not adversely influence the isolator pressurization.

Open aperture integrity

Open aperture protection is an important feature of some isolators. In addition to designing and testing for isolator pressurisation, some isolators need to be engineered to maintain segregation in case of partial or total glove loss. This is particularly the case when biological or chemical hazards are present internally, and need to be contained for safety reasons. Furthermore, in many production-scale isolator networks, particularly those filling parenteral containers, it is an advantage to pass the filled closed containers out of the isolator continuously via an airflow protected tunnel. In such cases, there is a protecting air velocity, entering or leaving the isolator, to contain a hazard or minimize the opportunity of internal contamination, respectively. The effectiveness of this inrush or outrush of air (protection factor) can be quantified by a biological or aerosol challenge test derived from adaptation of the method defined in British Standard 5726 (2) or the U.S. Standard NSF 49 (3). Both these standards relate to microbiological safety cabinets where the test is specified for the purposes of quantifying a containment factor. The containment test challenges the aperture with a test aerosol, and measures the quantity that escapes through the opening. The ratio of escape to generated quantity is used to calculate a containment factor. This test method can also be effectively deployed for testing and demonstrating the effectiveness of any other aperture inward or outward and is used to protect and segregate the internal from the external environment. In the classic case, there is a continuous discharge of filled containers across a dead plate, leaving an aseptic processing environment. Here it is important to determine that there is no turbulence causing induction of external contamination into the critical aseptic zone.

CLEANING AND SANITIZATION OF ISOLATORS

Effective cleaning and biodecontamination of the internal surfaces of isolators and their intimate product contact parts is of greatest importance, particularly for aseptic processing. The effectiveness and repeatability of the sanitisation method also has an impact on the quality of the surrounding environment required. This is particularly the case if it is anticipated that batch and machine format changes are carried out with the isolator open. If this procedure is adopted, it is necessary first to minimize the introduction of room contamination into the open isolator, and then to apply an effective cleaning procedure. If some contamination has entered the device, it is essential to use a repeatable and effective sanitization or surface sterilization

method. The requirement to clean and disinfect would be lessened if changeover were achieved with a closed isolator. The least effective processes, such as surface swabbing and aerosol spraying with disinfectant, are unlikely to satisfy the requirements of a repeatable process of high efficacy. However, the use of highly controlled gaseous-phase processes, using materials such as formaldehyde, hydrogen peroxide, peracetic acid, and chlorine dioxide, can be very effective. These gaseous-phase processes are generally intolerant of soiling deposits on the surface. Therefore, the methods must be deployed in conjunction with effective physical cleaning.

DESIGN CONSIDERATIONS FOR THE SURROUNDING ENVIRONMENT

Finally, having taken all the above issues into account, and determined the type and nature of the isolator to be used and the quality of the surrounding environment, it is important to consider some of the broader issues relating to the design of the surrounding environment. It is essential to thoroughly consider all the attributes of the facility in which the isolator is placed, as this can have a major influence on the product. The facility in which the isolator is placed must provide a clear departmental separation from less critical adjacent activities. By layout and configuration, it must achieve the following:

- Provide appropriate physical security for the operation
- Control and manage access of personnel and materials
- Ensure the required background environment is maintained
- Provide the utilities required by the isolator

INTRODUCTION

Iontophoresis is a method of transferring substances to and from the body for therapeutic or diagnostic purposes by applying an electric potential to enhance their movement across biological membranes. The most common applications of iontophoresis involve the delivery of therapeutic substances across the skin, though there are numerous examples of the use of iontophoresis to treat conditions of the eye, ear, nose, and mouth. Iontophoresis can also be used to remove substances (e.g., glucose) from the body. A technique known as microiontophoresis employs a small capillary probe to study cellular function by releasing precise quantities of active substances.

Banga (1) has stated that Veratti made the earliest references to the use of an electric potential to enhance the penetration of charged substances into tissues in the year 1747. Stephane Luduc (2) is generally recognized as the most important early researcher in the field because of his comprehensive studies of iontophoresis described in the 1907 publication "Les Ions et les Medications Ioniques."

Today, iontophoresis of drugs across skin or mucosal membranes is a noninvasive (needleless) method where the rate of delivery is primarily determined by the magnitude of the applied current, making patterned and on-demand delivery possible. Commercially available devices are typically bench-top systems with discrete patches connected to a power supply by electrical cables. However, due to recent innovations in electronic circuitry and battery technology, iontophoretic treatments can be administered with small, integrated patch-like systems.

The most common therapeutic applications of iontophoresis are topical administration of lidocaine as a local anesthetic and dexamethasone for treatment of local inflammation (Iomed, Inc., Salt Lake City, Utah and Empi Corp., Minneapolis, Minnesota). In addition to these therapeutic uses, iontophoretic systems are commercially available for the diagnosis of cystic fibrosis. For example, the CF Indicator[®] (Scandipharm, Birmingham, Alabama)

and the Webster Sweat Inducer (Wescor, Inc., Logan, Utah) deliver pilocarpine to cause local sweating: sweat is collected and analyzed for high levels of chloride. More recently, iontophoresis has been used to extract glucose from the skin as a means of detecting hypo- and hyperglycemia (Cygnus Corp., Redwood City, California).

Although these examples demonstrate the successful commercial use of iontophoretic technology for topical delivery of compounds, transdermal systems for systemic administration of medicinal agents have not been widely employed. There is, however, heightened interest in this field because of potential medical and economical benefits offered by iontophoretic technology, especially for meeting the delivery challenges posed by new biotechnology compounds.

A schematic diagram of a transdermal iontophoretic system on skin is shown in Fig. 1. A source of electrical energy, such as a battery, supplies electric current to the body through two electrodes. The first electrode, called the donor electrode, delivers the therapeutic agent into the body. The second electrode, called the counter or receptor electrode, closes the electrical circuit. Each electrode contacts an ionically conductive reservoir, normally present as a liquid or hydrogel. The reservoirs are placed on the patient's skin and contain either the drug (for the donor electrode assembly) or a biocompatible electrolyte (for the counter electrode assembly).

TRANSPORT MECHANISM

The term iontophoresis encompasses several processes for moving molecules across the skin: electromigration, electroosmosis, and electroporation. Electromigration is the movement of charged ionic species in response to an applied electric field. This process is usually of primary importance for delivering charged drug species. The movement of charged species within a solvent can induce solvent flow by a process known as electroosmosis. This process is useful for delivering both

Fig. 1 Schematic diagram of an iontophoretic device on skin indicating the flow of ions in response to an applied voltage.

neutral and charged drug species. Electroporation is the temporary creation of aqueous pores through lipid bilayers by applying high-voltage pulses, typically 50–1000 V, across the bilayers of a biological membrane. This process is useful for delivering large hydrophilic drug species. For any given iontophoretic treatment, one or more of these processes may occur simultaneously and to a varying extent, depending on the magnitude and duration of the applied electric field, the composition of the donor reservoir, and the type of the tissue being treated.

The movement of charges due to electromigration is illustrated in Fig. 1. In this diagram, positively charged drug (D^+) and its counter ion (A^-) are formulated for delivery from the anodic donor reservoir. The cathodic counter reservoir contains biologically acceptable cations (C^+) and anions (A^-). When an electric field is applied, drug ions migrate into the skin and endogenous anions, mostly chloride, migrate from the body into the donor reservoir. Simultaneously, at the cathodic counter electrode, anions migrate from the counter reservoir into the skin, whereas endogenous cations, mostly sodium and potassium, migrate from the body into the counter reservoir. The movement of ions maintains local electroneutrality throughout this process.

For iontophoretic treatments involving placement of the system on the skin, the therapeutic agent in the donor reservoir must cross the outermost layer of the skin, known as the stratum corneum, which is the primary barrier to permeation of substances both into and out of the body. The stratum corneum's excellent barrier properties result from its unique structure: approximately 10–20 layers of flattened, keratin-rich cells cemented together by lipid bilayers composed primarily of ceramides. In general, lipophilic species are capable of traversing the stratum corneum because of their ability to partition into the intercellular lipid region. In contrast, most ionic and polar substances are largely excluded from this region.

At the typical voltages used in iontophoresis (e.g., 2–80 V), the nature and composition of the pathways in the skin remain matters of some debate. However, there is a growing body of evidence that the preferred path for ionic species across the stratum corneum is not spatially homogenous, but rather consists of a distribution of localized regions. These regions include endogenous shunt-like structures across the stratum corneum such as sweat ducts and hair follicles, but may also include pathways not associated with natural shunts. Direct physical measurements of the transport of model permeants through the skin of hairless and nude mice have shown that between 60 and 90% of the overall flux can be explained by such regions (3).

The rate of transport of a charged drug species across a biological membrane is generally modeled by the Nernst–Planck equation. This equation contains terms for diffusion, electromigration, and bulk convection. However, under optimized iontophoretic conditions the electromigration contribution is often much greater than that of the other two, therefore the expression for delivery of an ionic drug species is frequently simplified to include only the electromigration term. The molecular flow of drug is thus related to the electric current, according to Faraday's principle:

$$N = (t_d IM) / (z_d F) \quad (1)$$

where N = total rate of delivery, t_d = transport number (the fraction of charge carried by the drug ion), I = current applied across the skin, M = drug molecular weight, z_d = charge of the drug molecule, and F = Faraday's constant (96,485 coul/Eq).

Many researchers have used in vitro and in vivo studies to demonstrate that the rate of drug delivery is linearly proportional to the applied current over a wide range. Because studies are typically performed with a fixed skin contact area, this proportionality indicates that the transport number is a constant and not dependent on the current density. However, the transport number is unique for each drug, and is a function of the drug's mobility, charge, and concentration, as compared with those of other migrating species. These dependencies are summarized in the following expression:

$$t_d = \frac{\mu_d |z_d| C_d}{\sum_i \mu_i |z_i| C_i} \quad (2)$$

where μ_d , z_d , and C_d are the mobility, charge and molar concentration, respectively, of the drug species, and μ_i , z_i , and C_i are the mobility, charge, and concentration for each mobile ion that competes with the drug for transport across the skin barrier. Competing ions are those in the

formulation that have the same sign of charge as the drug (i.e., competing coions), as well as those ions in the body that have the opposite sign as the drug (competing counterions).

The transport number determines delivery efficiency; that is, the amount of drug delivered per unit charge passed across the skin. Because it is desirable to minimize current (for optimal biocompatibility and battery longevity), it is advantageous to develop a formulation that maximizes t_d . This can be accomplished by maximizing the mobility and concentration of drug species while minimizing, to the greatest extent possible, the mobility and concentration of the competing species. Simple measures to achieve this include incorporating the highest practical concentration of the drug in the formulation, as well as avoiding excipients or impurities that produce mobile coions in the formulation. Even if both of these measures are taken, a t_d value of unity (i.e., all current is carried by the drug ion) is still unattainable in practice, because of endogenous counterions in tissue (e.g., Na^+ and Cl^-). However, the efficiency-lowering effect of competing counterions can be reduced by exploiting the inherent permselectivity of skin. Permselectivity based on charge arises from the principle of Donnan exclusion. The skin has an isoelectric point of about pH 4. Therefore, for a formulation with a pH value below four the skin will have a net positive charge and favor transport of anions; and at a formulation pH > 4 , skin will have a net negative charge and favor transport of cations. Thus, at the physiological pH 7.4, skin should be negatively charged and therefore be *cation selective*.

Efficient iontophoretic delivery depends on the materials and excipients used in the system. Selection of appropriate electrodes and formulations are critical to maximizing the efficiency of iontophoretic treatments. The following sections will summarize key criteria for selection of electrodes and formulations for transdermal applications, however, many of the same principles are applicable to iontophoretic systems used on mucosa or implanted within the body.

ELECTRODES

Electrodes apply the driving force for ion migration and are therefore critical components of the system. They serve as the bridge between the electric circuit and the two reservoirs, and perform both electrical and chemical functions. During iontophoretic therapy, electrodes undergo sustained electrochemical reactions and thus

the migration of reactants is a critical functional consideration. In this aspect, electrodes used in iontophoretic devices are different from those of most other medical electrodes. For example, medical potentiometric electrodes (such as those used for electrocardiograms or electroencephalograms) undergo no net reaction because little or no electrode current is required by the measurement equipment. In other applications such as cardiac pacing or transcutaneous electrical nerve stimulation (TENS), the applied voltage pulses are extremely brief (milliseconds or less) or of alternating polarity so the net quantity of reaction products is not great. For these applications the management of electrochemical reactions is achieved merely by constructing the electrodes from inert materials, for example, gold, platinum, or stainless steel. In contrast, iontophoretic electrodes are usually inherently reactive materials and are chosen for their preferred electrochemical attributes, as is described below. Because of their reactivity, and also because electrodes contact the drug formulation directly and therefore the patient's body indirectly, it can be technically challenging to choose an electrode system that possesses adequate performance while avoiding adverse material and biological interactions during storage and use.

As indicated in Fig. 1, a transdermal iontophoretic system requires that two electrode assemblies contact the patient's skin. The donor electrode (also known as the delivery or active electrode) contacts the drug reservoir. The counter electrode (also known as the return or receptor electrode) contacts the counter reservoir and completes the electrical circuit by providing a path for the current. The two reservoirs are separated from each other and contact skin over a fixed area. The electrodes apply an electric field across the skin by converting electric current supplied by the battery into ionic current moving in the skin and body. In doing so, a Faradaic reaction takes place at the electrode/electrolyte interface. As described previously in this chapter, there is generally a linear dependence of the rate of drug delivery on this current.

The polarity of the donor and counter electrodes depends on the sign of the charge on the species to be delivered. To cause migration of positively charged species from the donor reservoir into the skin, the donor electrode must have a positive polarity (i.e., anode), and the counter electrode must have a negative polarity (i.e., cathode). For negatively charged species, the polarity is reversed, so that the donor electrode is the cathode, and the counter electrode is the anode.

A practical electrode system must meet a variety of performance, compatibility, and physical requirements. When possible, the electrode system should provide for

maximum drug delivery efficiency (i.e., the rate of drug delivered per unit current), operate at low voltage (i.e., <1 V), have adequate longevity (e.g., 24 h), and distribute the current evenly over the entire area of skin surface (e.g., 10 cm^2). The electrode will provide maximum drug delivery efficiency if it does not contain or produce any competing ions (i.e., mobile ions of the same charge as the drug ion). For optimum compatibility, the electrodes should be made of materials that are nontoxic and compatible with other formulation components such as the drug, excipients, and matrix material. In addition, they must not generate reaction products that are toxic or that adversely affect drug and excipient stability.

Two classes of electrode are the nonconsumable or inert type and the consumable or sacrificial type. Nonconsumable electrodes are made from nonreactive materials, whereas consumable electrodes are electrochemically active and are structurally altered by the passage of current during treatment.

Nonconsumable Electrodes

Early iontophoretic drug delivery systems (IDDS) used materials that were not consumed during use. Commonly used materials included metals such as stainless steel or platinum. Although these nominally inert materials may have long use and storage lives, they also have significant shortcomings.

In accordance with Faraday's Law, the operation of an IDDS requires redox reactions at the electrodes in proportion to the amount of charge passed. For nonconsumable electrodes, contacting an essentially aqueous electrolyte solution, electrolysis of water is the likely redox reaction. Therefore, the reaction at the anode is:

and at the cathode, the most prevalent steady-state reaction is:

Both of these reactions have a number of undesired consequences. The generation of H^+ and OH^- can shift the formulation pH, affecting both delivery efficiency (due to a shift in the skin permselectivity, formation of competitive ions, or alteration of the charge state of the drug) and skin tolerability. The gases that are produced can accumulate on the electrode or skin surface, interfering with the uniformity of current distribution. Furthermore, because these reactions take place at relatively high voltage, there is high power consumption and a risk of electrolytic decomposition of the drug or other excipients.

Some electrodes made from nonnoble metals, such as stainless steel, can release metal ions through direct oxidation at the anode, or indirectly by the creation of a caustic environment at the cathode. For example, nickel and chromium ions were released from a medical-grade steel anode following a few minutes of iontophoresis at $400\text{ }\mu\text{A}/\text{cm}^2$. These ions can be toxic to the body (4).

Chemical methods that mitigate the deleterious effects of unwanted reaction products can be divided into three categories: blocking their migration, neutralizing (e.g., buffering) them, and preventing their formation by addition of sacrificial redox species to the reservoir electrolyte. Migration blocking is achieved by isolating the electrolyte adjacent to the electrode from the drug formulation or from the body by using ion-exchange or size-selective membranes or coatings. For example, an anion-selective coating at a nonconsumable electrode composed of methacrylamidopropyltrimethyl ammonium chloride copolymerized with methyl methacrylate was found to prevent degradation of the drug oxymorphone at electrode potentials up to 800 mV by blocking migration of the drug to the anode surface (5).

Buffering agents can partially compensate for the generation of acid and base, but their duration of efficacy (buffering capacity) is limited by the quantity of buffer species present, and the addition of excess buffer salts can result in ionic competition. Ion-exchange polymers can effectively scavenge, neutralize, and immobilize generated reaction products (6); the advantage over simple buffer salts is that the polymer chains are immobile and therefore noncompeting.

Consumable Electrodes

As described above, approaches have been devised for resolving the disadvantages of nonconsumable electrodes. Although many of these schemes are simple in principle, their practical implementation can be difficult because of various physical, chemical, and biological requirements. A simpler alternative is to use consumable electrodes. Also known as sacrificial electrodes, they are altered by electrochemical reaction during operation. Appropriate consumable electrodes will have redox reactions that take place at low potentials, thus avoiding parasitic reactions (e.g., electrolysis of water, drug, or excipients) at the electrode surface. Also, the reactants and products of the redox reaction must meet formulation and biological compatibility requirements.

A sacrificial electrode has a finite operational lifetime, or capacity, defined as the amount of charge that can be passed before the reactants are effectively depleted. The

capacity of an electrode can be empirically determined, or can be calculated from the following equation:

$$Q = \frac{umnF}{3.6M} \quad (5)$$

where Q = capacity (mAh), u = utilization (fraction of reacting species available for reaction), m = mass of reactant (g), n = number of equivalents of charge per mole of reactant (eq/mol), F = Faraday's constant (96,485 C/eq), M = molecular weight of the reactant (g/mol), and the constant 3.6 is a conversion factor (C/mAh).

If depletion results in an open circuit, the electrode will cease to function. Otherwise if an electrically conductive pathway remains, the electrode will continue to function under suboptimal conditions (i.e., at a higher voltage where other redox reactions, such as water electrolysis, take place).

Use of materials and structures that maximize utilization of reactants are preferred, as this allows the electrodes to be thin while making the most economical use of the consumable electrode. Factors that limit utilization include a tendency for passivation of the active component (by formation of a uniform, insoluble, nonconductive product over the active surface), and formation of "islands" (electrical isolation of one or more active portions by nonuniform current distribution).

No single consumable electrode is ideal for all iontophoretic applications. Different materials meet different capacity needs, and because consumable electrodes consist of chemically reactive species, certain materials may be compatible with certain drugs or excipients but not all of them. The most popular electrodes are based on the silver/silver chloride redox couple. Silver and silver chloride have several advantageous characteristics: They are biocompatible, perform well, and have an established history of use in medical applications including sensing electrodes.

Silver as a Consumable Anode

The use of a silver anode in the presence of chloride or another halide ion in the electrolyte solution is the most commonly used consumable anode for delivery of positively charged drugs.

Metallic silver oxidizes according to the following reaction:

However, when chloride is present, it will immediately react with the silver ion, that is:

The complete reaction is therefore:

The final product, silver chloride forms on the surface of the silver anode and is electrically neutral and practically insoluble. Therefore, this reaction couple does not generate species that compete with cationic drugs for delivery. Because the equilibrium potential is low and the reaction is kinetically fast, the silver anode operates at low voltage, avoiding undesirable side reactions such as water splitting or electrochemical degradation of the drug or excipients. The rapid reaction kinetics and immobility of silver chloride make the system highly reversible. A reversible electrode system is especially attractive in an alternating polarity IDDS (i.e., one in which the drug is present in both electrode reservoirs and is delivered alternately from each as the current is reversed). The electrode is effectively discharged on one phase of the cycle and recharged on the other phase, leading to extended capacity.

There is one significant limitation to the use of silver as an anode to form silver chloride. The silver surface of the electrode gradually passivates as the silver chloride layer builds up, causing an increase in discharge voltage with use. This passivation process can limit both the maximum allowable current density and the utilization of silver.

Chloride Ion Management with Silver Anodes

For optimal silver anode function, there must be sufficient chloride ion to react with the silver ion. When the anode is the donor electrode (i.e., delivers positively charged drugs), the addition of chloride salts can lead to ion competition and reduced delivery efficiency. To minimize cation competition the preferred method of adding chloride is by using the drug chloride salt (7). Not all drug substances are readily available as chloride salts, but many can be converted to the chloride form by ion exchange or to the hydrochloride salt form by protonation of amine groups through addition of HCl.

Because chloride ion is consumed as it reacts with silver ions to form insoluble AgCl, its concentration decreases during treatment. Chloride must be present in the electrolyte in sufficient quantity to ensure proper operation of the electrode throughout the therapy. If the concentration of chloride drops to the point where it can no longer scavenge free silver ions, there is the potential for silver to be delivered to the skin. The amount of bulk chloride in the electrolyte required to avoid silver migration depends on many factors, including the volume of the electrolyte, current density,

duration of treatment, the rate at which chloride is replenished from the body (i.e., the chloride transport number), and the configuration of the electrode and reservoir. Because interaction among these factors is often complex, it is difficult to construct a generalized model purely from first principles. Rather, for a given electrode/reservoir combination, it is often simpler to experimentally determine the threshold chloride concentration at which silver migration begins to occur, and then use a mass balance calculation to compute the required starting composition. A helpful indicator of silver migration is the potential of the polarized silver electrode. As chloride becomes less abundant, the silver anode voltage increases in a Nernstian fashion. Empirically, it has been found that operation of the anode above approximately 400 mV (vs. Ag/AgCl standard reference electrode) can lead to free migration of silver ions (5).
